Title: Lewis’s child and adolescent psychiatry : a comprehensive textbook / editors, Andrés Martin, Fred R. Volkmar, Michael Bloch.
Other titles: Child and adolescent psychiatry

We dedicate this book

To our wives:
Rebecca, Angie, and Lisa;
To our children:
Max, Ariela, Gabriela, and Jacob Donald; Rachel, Sam, and Tom; and Lucy and Emily;
To the teachers and mentors from whom we have received so much;
To the patients, families, students and colleagues to whom we hope in some measure to have given back;
To all those dedicated to child and adolescent mental health, working each day to make a difference.

As editors we are proud to donate our royalty proceeds, in loving memory of our teacher and friend, the late Melvin Lewis, to the Break the Cycle initiative of the American Academy of Child and Adolescent Psychiatry. The Academy continues to support efforts in education, training, and research for the next generation of practitioners, a mission that was near and dear to Mel.
We ourselves have been the grateful recipients of such support, and are honored to contribute so that others may benefit like we did.

FOREWORD TO THE FOURTH EDITION

A WORD is dead
When it is said,
Some say.
I say it just
Begins to live
That day.
— Emily Dickinson

The Belle of Amherst hit the nail on the head. Words are living things. And Emily Dickinson gave them meaning, with a new style, well ahead of its time. Words give meaning to our work, too. They form our knowledge base, which is itself a life in words that is always evolving. Yet basic developmental principles beneath that changing knowledge base offer continuity as well. Change mixed with continuity. That's what a textbook should offer.

The original *Child and Adolescent Psychiatry: A Comprehensive Textbook* was the first one published in our field since Leo Kanner's classic *Child Psychiatry* half a century before. Since then a number of other texts have been published, forming the excellent selection available today. But the latest edition of this volume continues to be the cornerstone of my library, and the first choice of many other child and adolescent psychiatrists. Its encyclopedic scope offers a broad reference that serves as a foundation for our field, as well as offering answers to the questions of everyday clinical practice and posing new ones that have yet to be answered.

A word about its development: Melvin Lewis, the pioneering editor of the first three editions of the *Textbook*, has given over responsibility for its fourth edition to the next generation—to a pair of valued colleagues with whom he has worked for years. The first, Andrés Martin, also follows in Lewis's footsteps as editor of the *Journal of the American Academy of Child and Adolescent Psychiatry*, a periodical that contains the cutting edge of research in our field. He is joined by coeditor Fred Volkmar, a distinguished scholar and world-renowned researcher in the area of autism. Together, they have assembled an impressive list of experts as contributors to this fourth edition.

A published book is a finished product, but it doesn’t begin to live until its words are read and discussed, its inaccuracies debated and corrected, its truths corroborated and its hypotheses tested. *Lewis’s Child and Adolescent Psychiatry: A Comprehensive Textbook, Fourth Edition* illustrates so well the changes in child and adolescent psychiatry, but it also insists upon the continuity of our field, teaching us how to listen to the young voices who are just setting on their course. Its words are alive; in them are both the continuity and the changes that are our field.

John F. McDermott, MD
Professor of Psychiatry Emeritus
University of Hawaii School of Medicine
Editor Emeritus
Journal of the American Academy of Child and Adolescent Psychiatry

PREFACE TO THE FIFTH EDITION

Lewis's Fifth

It has been exactly a decade since the publication of *Lewis's* last edition. We are delighted to present this latest iteration, its fifth. We have sought to maintain and expand in it the changes introduced in the previous edition, which represented a large departure from the three initial versions that Mel Lewis so diligently brought to life. Notwithstanding its changes, the current edition is true to Mel's original spirit and expands on the trajectory he began a quarter century ago, back in 1991. For the reader getting first acquainted with *Lewis's Textbook*, we have next included the preface to the fourth edition, in which we review the evolution of the imprint.

The changes in this edition are subtler than in the last. Most chapters have been updated and a select few have been left behind. Many have been entirely rewritten by new authors. The chapter on telepsychiatry introduces a topic that was in its infancy 10 years ago and has become all but standard today. The fifth edition of another book, the Diagnostic and Statistical Manual (DSM-5), also makes its first appearance in this edition, as does the Research Domain Criteria (RDoC) approach advanced by the National Institute of Mental Health over the past decade. A large and unwieldy chapter on psychopharmacology from the fourth edition has been carved out into five thematically linked, updated and more manageable component pieces. In a salute to our tradition and legacy, just as much to our field's vibrant practice and exciting future, we have left two meaningful components entirely unchanged: the foreword to the fourth edition, by the late Jack McDermott, and "Looking back, dreaming forward," the cautionary postscript by the late Leon Eisenberg.

One noteworthy change is the expansion of our original editorial duo. In this edition we have been joined by Michael H. Bloch—a younger colleague who did not have the privilege of getting to know and work with Mel Lewis like we did, and who is now enlisted, along both of us and so many of the authors herein, to carry on Mel's legacy into the future. The three of us wish to express our gratitude to the Wolters Kluwer team superbly orchestrated by Ashley Fischer, Rebecca Gaertner, and Chris Teja on the editorial side, and to Linda Francis and David Saltzberg on the production side. Finally, and as noted in the dedication page, we are proud as editors to direct our royalties to the American Academy of Child and Adolescent Psychiatry, an organization that Mel served so well and for so long. We hope this will not only honor his memory, but help in very tangible ways to further the overall goal of

Lewis's Textbook : to train and inspire a new generation of clinicians whose life's work is easing the burden of mental illness and improving the lives of children and families everywhere.

PREFACE TO THE FOURTH EDITION

Lewis's Fourth

[T]he mission ... is not to pass on an unchanged truth through a succession of the learned but to host the endless labor, carried on from generation to generation, needed to come closer to the truth: the work of challenging the adequacy of what currently passes for the truth, attempting to seize it more fully, and making that understanding available to others so they can move beyond it to a yet fuller realization.

—Richard Broadhead: Free Speech and its Discontents (2004)

Readers acquainted with the three earlier editions of this volume are as likely to be reassured as they are to be disoriented on seeing this latest version. The reassurances will come from the textbook's signature heft and color, a similar breadth in scope and depth in coverage, and the welcome resurfacing of many familiar names within. The disorientation should be slight but significant, perhaps beginning with the very name of the book, subtly but most certainly different from its predecessors'. The landmark *Child and Adolescent Psychiatry: A Comprehensive Textbook* that first appeared in 1991 had reached second and third editions within just eleven years (in 1996 and 2002, respectively). Today, 16 years after it first appeared onstage to set a new standard in the field, its latest edition comes forth, under the slightly altered title of *Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook.* The one-word change is at once subtle and momentous.

In this fourth edition, Melvin Lewis, for whom this landmark text has been a labor of love, makes way for two of his colleagues and students (not to mention admirers and friends) to continue his editorial vision and commitment. The book's new title reflects more than a semantic detail: in a fundamental way, *Lewis* embodies Mel's legacy and the values he has held dear for decades. His has been a model of professional and scholarly comportment that the two of us emulate each day. We are grateful for the opportunity granted us, and aware of the responsibility implicit in the stewardship we have been entrusted. We have strived for a new edition that includes the best of our science; that translates and makes it accessible and applicable; that

provides cohesion for a rapidly evolving discipline; that welcomes and guides the novice as much as reminds the veteran of the richness of our work. An edition, in brief, that by becoming a vehicle to improve the mental health of children and adolescents will make Melvin Lewis proud.

This fourth edition's title and cover art are the first and most apparent differences, but not the only ones. Indeed, it is in its substantially revised, updated and reorganized inner structures that the book is very much a new edition. The better testament to *Lewis's* ability to advance Mel's legacy may be in how different, rather than in how similar, it is from earlier versions. An evolving discipline is reflected in organically changing books that refuse to become definitive: Gauging from the changes to this tome from a mere five years ago, our field is a lively and thriving one.

An Approach to the Discipline, the first of seven sections, sets the tone for the volume as a whole. If there has been a guiding principle in assembling this textbook, it has been our effort to trace the links between multiple components of our field. We sought to identify continuities across the domains of clinical practice, research, training, and policy—a mutually enriching interplay at times more aspired to than real. We have opted for a reorganized structure in which aspects as varied as economics, diversity, or evidence-based practice are not treated as afterthoughts. To the contrary, we see such topics as a necessary foundation upon which to build. We have been deliberate in our choice of a first chapter that begins with the clinical care of a single child and ripples outward toward familial and societal dimensions: The care of children and families remains not only our foremost concern, but the place from where our major insights have almost invariably come.

The second section, *Scientific Foundations*, synthesizes three major domains of critical relevance to advance our knowledge base in childhood psychiatric disorders: epidemiology and prevention, genetics, and neuroscience. While this section could never be all-inclusive, it does aim to provide a basic level of scientific literacy required to be an informed consumer of the literature; one aware that today's arcane and seemingly esoteric finding may hold the key to tomorrow's breakthrough intervention. To provide a framework for understanding these or any other pertinent scientific approaches, the section includes an overarching chapter on research methodology and statistics.

We pause here to note with sadness the untimely passing of our colleague Robert Harmon during the making of this book. The very first chapter that we received came from Bob and his colleagues in Colorado. *Methodology and Statistics: A Relevant Primer and Overview* arrived with a characteristically encouraging and upbeat message from Bob. Of note, it appeared in our inboxes a full two days before the very first deadline, one so fashionably ignored by the other authors—ourselves included. We remember Bob with affection, and thank him not only for teaching and writing skills we all admire, but for punctuality that is an editor's dream.

The third section, *A Developmental Framework*, chronologically follows normal

development from the prenatal period through late adolescence. While incorporating the more relevant theories of human development, its chapters have a stronger emphasis on clinical applicability than encyclopedic coverage of specific milestones or schools of thought. The section is very much in line with our experience of Mel's teaching and is capped with a review of developmental psychopathology, addressing the ways in which genetic endowment and environmental conditions can interact along the dimension of time to increase the likelihood of resilient or pathologic outcomes.

A fourth section on *Nosology, Classification, and Diagnostic Assessment* starts with an overview of the different ways in which child psychopathology has been historically classified. This chapter identifies differences across, and within, the major nosological schemes: the European ICD versus the American DSM, and the various iterations of the latter. Although this discussion will eventually be eclipsed by the arrival of the forthcoming DSM-5, the more relevant point to make here is that this volume is not beholden to any given system: we have not imposed editorial consistency at this level, realizing that such classification schemes are fluid and perfectible products. Thus, some chapters stay within well-demarcated diagnostic lines, others see the limitations in existing criteria, while yet others take whatever is useful from different classifications. The longer part of this section is dedicated to the diagnostic and clinical assessment process, and includes chapters that range from specific forms of assessment to the integration of the rich complexity inherent in child psychiatric practice.

Specific Disorders and Syndromes is the fifth and longest section. We should note here that for many conditions we have followed groupings that made good clinical sense to us, even if our organization scheme was not necessarily the most traditional. The same can be said of the part on treatment in the sixth section, where we created a *Continuum of Care and Location-Specific Interventions* category that, while wordily titled, brings together aspects that are often as poorly articulated in textbooks as they are out in the community.

The seventh and final section encompasses the very broadly ambassadorial *Interface Areas of Child and Adolescent Psychiatry*. Specifically, it includes our discipline's work on the borders—and often well within the territories—of pediatrics, schools, and the law.

Lewis comes up to 87 chapters, 155 contributing authors and over 1000 pages of text. What if anything can we make of these summary and impressive statistics? And what can we make of the fact that it has 46 *fewer* chapters and a significantly different line-up and content than its previous edition? More importantly, how does a discipline know that its knowledge base is moving in the right direction? When its truths become pickled into canonical and unchanging texts, or when they squirm out of our grasp and refuse to be fixed? When their tomes become thicker? When they become leaner? Perhaps it is when the tomes disappear altogether?

These questions are not rhetorical, nor are they simply meant to provoke. The fact is that books today are not what they used to be just a decade ago, and the place and function of the academic textbook needs to be reconsidered in light of today's hegemony of the internet as a source of living and constantly shifting knowledge. Knowledge that in turn brings up a whole new set of questions about the information available to clinicians, practitioners, and patients: What is the least disorienting and most reassuring source of information after all? Do not get us wrong: neither one of us is a pessimist. We are proud of this book and confident that it will teach and, we hope, inspire the readers it reaches, that it can provide a sense of overarching coherence one would be hard-pressed to find elsewhere. But we are realists and aware that some of the information contained in these pages will be out of date even before the book sees the light of day and that some more will gradually decay like so much radioactive material. The problem we now face is finding some sort of effective rapprochement between nimble cybernetics, with its propensity to conflate the constructive and responsible with the misleading and reckless through a simple mouse click, and the solid consensus of the textbook, where rigorous methodology and transparent use of science and sources also risk reifying what is incorrect as authoritative.

Lewis's previous edition was already available as an e-book that included hypertext links. This new edition follows suit with updated technology, and a shorter, pocket companion version with self-assessment questions is planned. In these ways, this traditional textbook will continue to advance into electronic territory. As we look at the first three editions sitting on our shelves, we think back to the shelf of Professor Victor McCusick, father of modern human genetics and editor of the classic *Mendelian Inheritance in Man* first published in 1966. During the years under his watch, genetic information exploded, such that his svelte single tome evolved into a massive three-volume 12th edition by 1998. Paper stock and wet forests shuddered at the thought of what the next edition might entail. As it turns out, it entailed very little, at least by ways of paper: By then the resource had all but ceased to be a book, having migrated almost entirely to the web as OMIM (http://www.ncbi.nlm.nih.gov/omim).

Even as this and other textbooks are likely to continue merging, blending, and otherwise becoming complementary with electronic resources, we do not hold our breath for a complete migration to the web. But even if there is one, we wager that there are abiding values and clinical wisdom in these pages that will continue to hold true and guide our practice for years to come. The very first and the very last contributions to this communal effort reassure us of as much: we are indebted to Jack McDermott for his foreword, to Leon Eisenberg for his postscript, and to both for standing as beacons who direct us toward values and principles worth holding dear.

We are grateful to the superb lineup of contributing authors for their engagement, responsiveness and excellent work. We thank our advisory board members for their

input and sage advice at critical junctures en route to the palpable reality of this book. We express special thanks to a Lippincott Williams and Wilkins team superbly orchestrated by Charley Mitchell. And to end as we began, our gratitude and deep appreciation to Melvin Lewis, whose passion and vision were the original ingredients for this textbook's secret recipe. Grateful though we are, we humbly recognize that the success of this edition should be measured by how much it helps move our field toward the fuller realization of helping children and families everywhere.

SECTION V: SPECIFIC DISORDERS AND SYNDROMES

SECTION I

AN APPROACH TO THE DISCIPLINE

CHAPTER 1.1 ■ THE ART OF A CHILD, FAMILY, AND SYSTEMS-CENTERED SCIENCE

KYLE D. PRUETT

> *I keep picturing all these little kids playing some game in this big field of rye … Thousands of little kids and nobody's around—nobody big, I mean—except me … What I have to do, I have to catch everybody if they start over the cliff.*
>
> —J.D. Salinger, *The Catcher in the Rye*

INVITATION TO THE PRACTICE OF CHILD AND ADOLESCENT PSYCHIATRY

Like many medical students before me, I had been moved and troubled by my first encounters with the mind-shattering onset of schizophrenia in adolescence: such pain and disorientation during such a promising era of life. There had to be better ways to understand and reduce the morbidity of such illnesses for these young people and their families, or at least to catch them before they edged Holden Caulfield's cliff.

Such thinking diverted me from pediatrics and adult psychiatry toward working with ever younger children, looking earlier and earlier for how to be of use. I eventually found myself standing by NICU bassinettes of poorly thriving infants with anyone I could corral to help me fathom how things could go so wrong, so soon, and too often with the very young. I found smart, humane mentors in child psychiatrists Al Solnit (Yale Child Study Center), pediatricians Sydney Gellis (Boston Floating Hospital) and Sally Provence (Yale Child Study Center); each one discouraging simplistic formulations and helping me embrace the complexity of early experience with all the rigor I could muster.

It struck me that child and adolescent psychiatry had it right. The earlier the better—for diagnosis, treatment, parent guidance, cost–benefit ratios, and whatever we could do to help families support, and grow with, their vulnerable and promising children. It also struck me as shortsighted to dissect the child out—even intellectually—from its family for diagnostic studies, economies of time, convenience of intervention, ease of insurance, billing or cost containment. Such a myopic approach was like a celestial navigator trying to identify a constellation by fixing a solitary star with his sextant; then as now, a guaranteed way to get good and lost.

So, how to stay on course in this odyssey to effective intervention and prevention? We now know, thanks to the advances in epigenetics, that we must consult both the gene map (nature) *and* family tree (nurture) and experiences that bridge them to stay on course. From the beginning of developmental mental health explorations in the 1920s and 30s, child psychiatry distrusted the facile nature versus nurture dichotomy offered up as dogma by so many behavioral scientists. Careful clinical investigations

and longitudinal inquiry repeatedly fell short of affirming it as the best way to formulate helpful interventions.

Contemporary science has all but eliminated this distraction, helping us to conceptualize the dichotomy less as competition, and more as a transaction (1). It has proven more illuminating to investigate how we nurture nature than to officiate at the face-off between the two. Tienari et al. (2) highlight clearly the interaction between environment and genome as accounting for more of the variance in clinical outcomes of illness than either genetics or environment alone. The compelling early studies by Caspi et al. of G(ene) × E(xperience) (3), and Kaufman et al. (4), and more recently Yehuda et al. (5) and Meaney (6) of gene interactions and environmental modifiers of depression in children provide elegant empirical grounding to that effect. Taken together, their work addressing G × E interactions between severity of child abuse, 5HT transporter polymorphisms, and outcomes of depression and conduct disorder have profound implications for societal and mental health intervention.

The outcomes of well-designed longitudinal studies of young children and families at risk also encourage us to focus on this discourse between gene and environment to design more effective and relevant service, policy, and research agendas (7). Sroufe et al. (8) concluded from his classic *Minnesota Study of Risk and Adaptation from Birth to Adulthood* that "early history is not destiny, important as it is … [D]ata suggest a renewed focus on the lived experience of the child and [less] preoccupation with inherent biologic variations."

This perspective can save us from a too myopic focus on the behavior of the child as we struggle to understand ways to decrease the morbidity of psychopathology and increase resilient contexts which, in turn, lessen comorbidities. Hechtman's (9) discussion of research into long-term outcomes of childhood disorders encourages us to cast a broad net in our search for the salient factors affecting outcome which extend beyond behavior. She reminds us to look beyond age, gender, IQ, comorbid conditions, physical, and emotional health to include socioeconomic status, family function, and composition, and child rearing practices. Felitti and Robert's (10) work on the long-term negative health sequelae of adverse childhood experiences makes a most compelling case for this approach.

It is the ability to embrace this complexity—not avoid or oversimplify it—that defines child psychiatric clinical competence. Authors have tried to conceptualize this visually by drawing concentric circles outward from the child to include all the factors that shape development, per se; particularly when we adhere to classical definitions of development as the melding of genetic predisposition, or maturation, with experience. But such visuals typically fall short, because as Spitz (11) so efficiently summarized four decades ago, "Maturation is a useful concept, but in reality there is only development." Ultimately, it is the environment that processes any given child's genetic blueprint, through maturation, into lived experience.

The core purpose in diagnostic and intervention strategies is to encompass and

embrace the complexity of the child's experience to understand and treat, while fully incorporating the hegemony of age (chronologic and developmental) and circumstance. This is precisely what obligates the researching and treating physician to employ the child-, family-, and systems-centered approach embraced throughout this textbook.

Families render humans human. Era-specific developmental forces within the family and the child jointly define the salient relationships and intimacies that draw the infant in one human transaction at a time. The family in all its permutations ultimately embraces that particular child's maturational promise and, through powerful reciprocal forces, converts tissue, synaptic connection, and instinct into human development. Although family processes seem linear (from birth and growth to decline and death, repeated ad libitum), family process itself seems more helical in form. Each generation must accommodate its own unique life cycle agenda. Consequently, it may be more helpful to visualize family processes as intertwined developmental courses, not unlike Watson, Crick, and Franklin's double helix. Winding side by side, the generations develop together, intimately connected with, but nevertheless distinct from, other generations in the family.

This helical image of family development consists of two distinct conceptual strands. One strand is the family's trail of generational myths, expectations, attributes, memories, and secrets—the family's "givens." This is the family's narrative about itself, eloquently described by Pincus and Dare (12) and Vangelisti (13). The narrative evolves much like folk songs in the oral tradition, passed on at home, as children are taught who and what their family has been, and is hoped or expected to be.

The other strand is the family's forward progression through time in the here and now. This encompasses the usual stresses and opportunities of the family's children's developmental requirements and the intrusion of "fateful events," both positive and negative. How the family copes with the course of development, accidents, and intrusions from outside and within is determined in part by whether these two strands intersect at strong or weak points. Real trouble seems most likely when a vulnerable stretch on the transgenerational strand intersects with an equally vulnerable stretch on the developmental strand.

For example, the Jones family narrative carries the myth/expectation that "Jones boys always marry wild women" at a time when, on the developmental strand, the Jones' first born son is starting his adolescence by easing up on his typical and historic academic discipline and atypically, for him, testing behavioral boundaries. He tells his parents progressively less about his life and whereabouts (appropriately), especially where girls are concerned and voilà—his and his family's fantasies about "wild women" fuse and sparks fly. Unless the clinician has some awareness of this fraught intersection of the Jones' family brand of developmental and transgenerational vulnerabilities, he or she may be too quick to

assign an impulse or other behavior disorder label, which in turn, might lead to ineffective or inappropriate intervention.

Family development as a dynamic phenomenon is particularly hard to fathom because clinicians tend to encounter families at but one nodal point in time, denying them a critical longitudinal perspective. Classic and current research suggests strong links between early loss, trauma, and disturbance in the family and later interpersonal dysfunction (14–16). At any given time in our interaction with a family, we may be uncertain about which direction the causal links may be moving (such as whether a vulnerable child destabilizes the family, or vice versa) (17); most mental illnesses are not the result of a sole inborn factor, or some single extraneous perturbation, but rather the multiply determined end result of human development gone (momentarily, one hopes) awry.

THE EVOLVING FAMILY SYSTEM

Most sociologists opine that the range of family structure continues to evolve. Lower birth rates, substantial (though stabilizing) divorce rates, older age of first child births (26 in 2015 compared to 21 in 1970) increasing remarriage rates, accelerated same-sex marriage and step-family rates, and longer life expectancies have all reduced childbearing from being the major occupation of parents to what is now less than 50% of parents' lifelong commitment (18).

Typically, historians urge caution whenever referring to "unprecedented change." Demos (19), and Laslette and Wall (20), dispelled the myth of the ideal three-generational family holding sway in preindustrial family life, citing instead a social process over the past several hundred years, and in particular over the past few decades, that has effected major changes in family functioning. Hareven (21) summarizes "Through a process of differentiation, the family gradually surrendered functions previously concentrated within it to other social institutions. During the pre-industrial period, the family not only reared children, but also served as a workshop, a school, a church, and an asylum." The difficulties faced by contemporary families are rooted in this diminished capacity to adapt and cope (partly because of smaller size) and the further narrowing in the range of the family's socioeconomic functions and independence.

The declining maternal and child death rates of the 1950s, combined with a higher marriage rate and longer life span created a higher percentage of children growing up in stable, two-parent families than had ever occurred in America's history. Beginning with the 1960s, however, multiply determined trends began to reshape the ideal and real traditional nuclear family. The sexual revolution uncoupled the societal association of sexual and reproductive behavior, particularly for women. From 1971 to 2002, the percentage of unmarried American girls 15 to 19 years of age who engaged in sexual intercourse rose from 28% to 60%. Second, married women with

children moved into the paid workforce: There was an increase from the 1960 level of 19% of married women with children younger than 6 years of age in the labor force to a real figure of 66% in 2001. Historian Robert Griswold (22) noted that these forces, combined with attitudinal changes toward co-parenting, have brought increasing numbers of fathers into the nurturing domain, whether or not they want to be there.

Fertility and fecundity also declined in the United States beginning in the 1960s. We are now at levels lower than those necessary for the replacement of the population, having moved from an average of 3.7 children per woman in 1960 to 1.83 (23). Increased child survival over the last century, combined with women having their first children later in their reproductive years, may also be contributing to families having fewer children.

The divorce rate in America, though currently stable at roughly 38%, brought us past a landmark in 1974, when for the first time in our history, more marriages concluded in divorce than in the death of a spouse (18). The percentages of unmarried couples, same-sex couples, serial and stepfamilies, and single-parent families (single by choice or not) have all increased, whereas nuclear unit percentages continue to decrease.

Finally, many clinicians and researchers share the opinion that the quality of life for children in the past 40 years has not improved at the same rate as it has for adults. Also, rates of distress seem to be on the rise. Achenbach and Howell (24) studied the changes over 13 years in the prevalence of children in the general population with behavioral/emotional problems. They found more untreated children who needed psychological intervention in the 1989 sample than in the 1976 sample. The 2014 Kids Count Report by the Annie E. Casey Foundation documented a continuing downturn in child well-being trends with increasing child poverty and obesity, infant low birth weight and mortality, and a teen death rate increase over the previous 5-year report. This suggests that the trend noted by Achenbach has yet to reverse itself (25).

Though family structure continues to evolve to include different constellations within and across generations, most children continue to long for meaningful relationships with both biologic parents in his or her life (26). The family structure that is most influential in the child's development, however, is the one perceived by the child as his or her family, not the one perceived by the Census Bureau or any given research protocol.

Many contemporary statistics illustrate an important, irreducible fact about ongoing change in the American family: Most moms work some or full time (71%, 2015). The 2003 U.S. Bureau of Labor Statistics report (27) documented that 16% of all married couple families have a wage-earning father and a stay-at-home mother; that number was 67% in 1940. Child rearing families also tend to receive more societal and economic support when both parents are committed to the job in all its

complexity. Families have changed, particularly in expectations around co-parenting and paternal engagement, according to a recent *Zero to Three* Survey (28) yet the institutions the families rely on most heavily—schools, health care, and the workplace—have been slow to respond to these changes.

MOTHERHOOD AND FATHERHOOD

Each child who enters the family changes it permanently, rendering each child's perception of their family as unique in, and to, their own experience. Sameroff and Fiese have moved us away from the restrictions of the linear, interactional model of child development, and toward one that better encompasses the progressive, dynamic, reciprocal forces that have helped children change families and vice versa (1). Their "transactional model" emphasizes the need for incorporating social and economic as well as biologic forces, proposing instead a "continuum of caretaking causality," with increased emphasis on the qualitative aspects of the nurturing domain. It encourages clinicians and researchers to think anew about who in the family is doing what with the children, and not simply how long they are doing it.

The Berkeley Adult Attachment Interview (29) in its application to family development (30) is an example of our growing skills in assessing the mother's and father's separate states of mind (and not simply their behavior) with regard to attachment to their children, and vice versa. As such it exemplifies how we are returning to the exploration of the overriding significance of the quality, sensitivity, and intent of the nurturing interaction, and not merely the biologic predispositions of the interactors. Mothers, fathers, grandparents, aunts, uncles, and siblings—all form unique attachments that, in formative settings, are welcomed and easily integrated by the child into a mosaic of consistent, predictable, stabilizing internalizations of the nurturing experience. We are now aware that attachment behavior between mother and child is obvious within the first months of life and is centered on establishing a sense of comfort and security, especially when the child is stressed. Attachment behavior between fathers and children becomes defined later in development, when the child is more mobile and more likely to test the limits of safety through risk taking. Managing the excitement of novel exploration and remaining safe when doing so is more typical of paternal attachment behavior than of maternal attachment behavior (31,32). Internalization of the nurturing experience, be it positive or negative, is not merely the result of a single adult attachment, but rather of the mosaic of the infant's experience with meaningful relationships over time.

Optimal family development, as perceived by the child, begins with a secure individual relationship, which the infant typically makes with its primary caregiver, typically the mother. Fathers can also form such attachments, rearing their children without placing them at developmental risk (33–35). Radin and Harold-Goldsmith (36) and Pruett (35) cite the advantages to young children of paternal involvement,

independent of the reasons for the father's presence (29). The other optimal phenomenon for promoting development in the family network consists of the capacity of mothers and fathers to form reciprocal, empathic, and unique relationships with the child, aided by a broad and complete range of affective expression. Both parents must be ready to accept developmental progression and change, because it comes rapidly, particularly in the first year, aided by appreciation for the child's idiosyncratic traits, temperament, skills, and vulnerabilities.

Much clinical literature, however, falls short in clarifying distinct maternal and paternal antecedents to psychological syndromes (37). When Bezirganian et al. (38) found that maternal overinvolvement, paired with maternal inappropriateness, combined to form pathogenic predispositions toward borderline personality disorder in children, paternal measures, which were included, were not commented on in their discussion. Despite the dramatic increase in the number of publications on fathering since the mid-1980s (39), fathers continue to be vastly underrepresented in the clinical and research literature, though fathers are now more engaged with their young children than in any era since the Industrial Revolution; the father's share of childcare more than doubled between 1965 and 1998 (40). A typical example of how this remains neglected in the literature: A major prospective, longitudinal study on parental psychopathology, and parenting styles as related to the risk of social phobia in children failed to include any data on fathers (41). Panter-Brick's (42) important global review of paternal engagement literature found that the vast majority of published literature in peer-reviewed journal rarely includes paternal measures or variables, much less correlative findings, even when "parents" is in the title of the paper.

Phares and Compas (43) reviewed research papers in the major journals dealing with clinical child development published from 1984 to 1991 and found that nearly half of all studies involved mothers only. Nearly one-fourth of the remaining studies did include father-related material, but did not differentiate its effects. The final one-fourth did measure father–child effects and found them consistently present. So, when researchers do bother to look for father effects, they typically find them. The authors suggested that the overreliance on mothers as research participants has fostered not only an incomplete data set with regard to child development, but also one that is heavily gender biased because "relations cannot be found among variables that are not investigated (43)."

EVALUATING THE FAMILY

As child psychiatrist works to understand the child's experience despite such lacunae in the literature, he or she is best served by viewing the family as a system, in which change in one segment of the family resonates throughout the system; promoting or discouraging development in other family members. Families must "raise the

children" while socializing their young, balancing risk and protective factors (44), and simultaneously meeting the demands of rapidly evolving maturational forces in the child. It is crucial, then, to appropriately evaluate the family system's potential for preparing its children for adulthood.

Skinner et al. (45) created the classic Family Assessment Measure, consisting of a general and dyadic scale to distinguish reliably between normal and problem families. Mrazek et al. (46) developed the Parenting Risk Scale, which uses a semistructured interview to rate difficulties and concerns regarding parental commitment, knowledge base, control, psychiatric disturbance, and emotional availability. The McMaster Family Assessment Device is a questionnaire filled out by both parents to assess seven categories of family functioning (47). Fleck (48) described an efficient, five-factor method, based on a family interview, for assessing the family's capacity to support the development of its children across its life cycle, consisting of (a) leadership, (b) boundaries, (c) emotional climate, (d) communication, and (e) the establishment and accomplishment of goals and tasks throughout the life cycle.

Leadership is the decision making, facilitating source of power and discipline used by the parents to lead the family forward (or not). It is shaped by the presence or absence of mutual support and regard, and by the effectiveness of the communication between the leaders of the family unit. Leadership itself is complex, as seen in the work of Minuchin and Fishman (49), who have tracked its migration between family members and generations, depending on the particular mix of strengths, vulnerabilities, or developmental demands that are preoccupying the family at any given moment.

Family boundaries refer to boundaries (a) within the individual that define the self, (b) between generations, and (c) between the family and the community. It is important that these boundaries be semipermeable, permitting contact and discourse with others outside the family boundary. Self and generational boundaries tend to remain stable throughout the life cycle, whereas family/community boundaries must become increasingly permeable as children cross them with increasing frequency to participate in the community around them.

The emotional climate, or affectivity, of the family unit is the connective tissue that binds the family together as a functioning unit. It sustains—or erodes—the family's capacity to care for and support itself and one another, especially since the family has ceased to be such a self-contained economic unit. Chronic scapegoating of a family member, child abuse, interpersonal violence between parents, and neglect are classic signs of failure in the family's emotional climate.

Communication within families is obviously both verbal and nonverbal. Communicative language and its uses for deepening relationships are learnt best within the family, assuming a healthy emotional climate. Experiences and affect are shared through the medium of language verbal and nonverbal, whereas values and

culture are differentiated and reinforced by the consistency, tone, and content of communication within the family.

Finally, the expectation that families will nurture and socialize their young so that they develop into contributing members of society is the moral obligation placed on these functions. The success or failure of this expectation is determined by the way the family achieves its goals for individual members and sets the members' tasks toward reaching those goals. Goals and tasks throughout the life cycle change and evolve in complex ways and, unlike communication or boundaries, seem not to diminish in significance over time.

Cultural influences powerfully shape the tasks of the family across the life span. As child-rearing domains become increasingly complex, it is essential that clinicians and researchers remain vigilant for the health-promoting cultural and functional forces that frame a particular family's expectations, resources, strengths, and vulnerabilities in their context (35,50,51). Values about dependability, family loyalty, intimacy, privacy, autonomy, and extended family access vary widely and normatively across the whole range of families created by adoption and assisted reproductive technologies (52,53).

Appreciating particular values in context is critical for the growing number of children raised in families shaped by multiple cultural influences. Social and cultural isolation of such children and their parents can frustrate the resilience and strength so common in the families that adopt cross-racially, or a multiply fostered child, making their task unnecessarily more complex. Same-sex parenting partners and their children can experience conflict in certain communities stemming from the failure to appreciate such a family's contextual needs and competencies (54), rendering the children at greater risk in certain developmental stages, especially the transition to adolescence (55).

THE ARTS OF CHILD PSYCHIATRY

Having defined the parameters of the task, we can look in greater detail at the skills on which child psychiatrists rely to help them accomplish their goals, and what, if anything, is contributed by an artful or humanistic approach to their work. Child psychiatry as a field has had a historical influence on the country's general attitudes toward the needs of its children that is out of proportion to its number of practitioners. Child psychiatrists figure so prominently in the creation of the fields of mental health consultation and crisis intervention that one may ask "Why them?" Why have they consistently held seminal leadership positions in public policy, from the landmark Joint Commission on the Mental Health of Children in 1965 right up to the Neurons to Neighborhoods Report of the National Institutes of Medicine in 2002? Why did the nation's media turn to them for consultation and guidance following the events of 9/11/01, the mass shootings in Newtown, CT, and more recent acts of

terrorism, both local and global? Why this trusted provenance in the well-being of all children, and not simply the mentally ill, from this medical subspecialty at the local and national level?

Attempts at defining *art* are instructive in understanding this penchant for hard-headed soft-heartedness among child and adolescent psychiatrists. The OED's "skill in doing anything as a result of knowledge or practice" definition suggests that medical training in and of itself prepares and predisposes these practitioners and researchers to embrace interdisciplinary thinking automatically. Such thinking is essential to understanding child development, as one is constantly juggling competing theories to understand a particular child and family's vulnerability, be it behavioral, psychodynamic, cognitive, or all of the above. So, when it comes to working with a team on an inpatient unit, a military base or in school consultation, it is already second nature to welcome and be informed by other "systems" of understanding. It is likewise second nature to be thinking differentially about case-based diagnostic and symptomatic material the moment it is encountered.

A further OED definition of *art* reads, "human workmanship as opposed to natural [ability]." The ability to listen with nonjudgmental patience, discriminating care, and open mindedness to children's verbal *and* nonverbal communication is one of the hallmarks of this specialty's competence. So many of our young patients trust us because they feel heard by us. This skill at listening to behavior, symptoms, play, artwork, or rationalizations develops over time in the clinic, supervision, team meetings, emergency departments, the movie theater or the waiting room, and eventually starts to resemble a "knack." However, as a teacher and supervisor of hundreds of practitioners in this field for over three decades, I am more persuaded by the "work(wo)manship" argument for developing the "knack" than the "nature" one.

This particular skill or "intellectual instrument" undergirds the child psychiatrists' reputation for being among the best interviewers in medicine, whether the subject is child or adult. The daily experience with children and their families shapes one's judgment over time about what to ask and when, in investigating and fathoming the child's distress. The clinician knows that questions are never simply queries, but rather a medium for judgment, concern, comprehension, or indifference, depending on how and when they are asked, and how carefully they attend to the answers. It is in the art of the interview itself that the potentially caring/healing relationship is first introduced and subsequently shaped, and the empathic apprehension of the skilled listener/observer is established, whether with an individual child/infant, parent, couple, or entire family system.

Outside the interviewing domain, however, child psychiatrists also respect and embrace the complexity of the context in which the child of concern lives his or her daily life. It is this appreciation for contextual symptom expression that makes them so useful to the institutions that serve the needs of children in the community, and such effective advocates for policies that increase care and well-being of society's

most vulnerable; hence, their pioneering role in establishing mental health consultation in community agencies and schools (56,57), and crisis intervention in the first place.

This predilection for contextual information also renders typical child psychiatrists slower than the average general practitioner to prescribe medications with the potential to change behavior, understanding as they do the power of context, positive and negative, to influence behavior (58). The longer amount of time with the child and family utilized by the child psychiatrist may predispose toward this difference, but it remains more a perceptual than a time management issue.

Another perceptual distinction that defines the child psychiatrist's unique approach to understanding and studying mental health and illness is the enduring respect for the power of development to predispose to health. Child psychiatrists, therefore, habitually embed their understanding of a particular child's clinical presentation into the proper era/context of child and family development.

Family development itself is somewhat arbitrarily divided into sequential stages for better understanding of the predictable developmental phenomena typical of a certain era. This approach risks oversimplifying the complexity of the relationship system which expands or contracts to support the entrance, development, and exit of family members emotionally, culturally, and historically. I review these stages with an eye to the contributions made by the nurturers and the "nurturants," examining the unique and differing roles of mothers and fathers as participants and facilitators of normal development across the life cycle.

THE DEVELOPMENTAL APPROACH

Coupling and Family Formation

Making a deliberate decision about family formation predisposes toward child and family well-being, just as an unconscious, nonconjoint decision predisposes to developmental risk. One of the stronger unconscious motivations toward coupling is the wish to acquire in one's mate a longed-for or unfinished aspect of oneself. This can strongly predispose toward stability in a marriage and may have an ameliorating effect on eventual family formation despite previous negative experiences, particularly on the part of the mother in her own childhood nurturing interactions. Eichberg has found in her research using the Adult Attachment Inventory that the father's role is positively ameliorative of a mother's negative experience with her own parents (59,60).

When the coupling results in a stable, long-term relationship or marriage, it is a joining of two complex historical, interpersonal, emotional, and economic systems. Couples are marrying later and postponing birthing their children: the average age of first marriage for women in 2004 was 23.1 and for men 24.9 years, and the birth of

their first child came on average 1 year and 11 months later. In 2014 it was 26 for women and 27 for men. The rise in cohabitation rates, both planned and unplanned, however has kept first child age cohorts stable over the last 20 years (61). These numbers imply there is a relatively short time given to adjusting to this phase of life, and sociologists note that there is a relatively narrow window for the timing of this family preparation phase. Women are twice as likely to divorce if they marry before the age of 20 years as if they marry during their 20s. They are half again as likely to divorce if they marry after 30 years of age than if they marry during their 20s (62).

A variety of other factors also can contribute to difficulty at this life cycle transition: (a) the couple resides at either great distance or close proximity to either family of origin; (b) the couple meets or marries in close proximity to a significant loss; (c) the couple marries after knowing each other for fewer than 6 months or an engagement lasting over 3 years; (d) the wedding is performed without family or friends; and (e) the wife becomes pregnant before or within the first year of marriage (63,64). It does seem that the rise in women's socioeconomic and political status is correlated (though not necessarily causally) with some degree of marital destabilization and with the increasing, although not absolute, marital dissatisfaction of their husbands. We are clearly in a transition toward more egalitarian relationships, and the educational and occupational equity of the sexes can be a creative catalyst (65). In the recent revision of her classic sociology of marriage, Stephanie Coontz [2016] (66) summarizes, *"There is **not** growing estrangement or a widening gender gap in what women and men want from each other. Most men and women are moving in the same direction in terms of their values ... Tensions between men and women today stem less from different aspirations than from the difficulties they face translating their **ideals** into practice."*

How people are choosing partners, and who they are choosing has also changed, most remarkably with the use of online relationship brokerage, as trends in miscegenation and same-sex partnerships show, which brings new challenges, opportunities, strengths and stressors to the new family.

First Conception, Birth, and Nurturance

This era begins with conception and ends at the end of the child's first year. There is much psychological work to be done by both parents in preparing for and dealing with conception. There also is enormous variability in the amount of conscious deliberation devoted to the decision to conceive a child. Once conception does take place, planned or unplanned, complex psychological responses follow in both wife and husband. The mother struggles with profound changes occurring in most of the organ and hormonal systems in her body during pregnancy and after delivery. Fathers also undergo physiologic (hormonal and body mass) changes during pregnancy and the perinatal periods, most notably in increased in oxytocin and estrogen secretion

and decreased testosterone production (67).

Meanwhile, much of the psychological work is fueled by a conscious reassessment of the couple's own family experience. A new identity comes to fruition, that of being a parent, not just of having one (68). What makes this riveting is that both maternal and paternal identifications are deeply rooted in each parent. The mother prepares herself psychologically for the coming attachment to her infant by drawing her attention to her own inner experience and her growing fetus, as her preoccupation with the outside world decreases.

Fathers are involved in psychological work of a different sort, albeit active and equally important in terms of preparation. Food cravings, somatic preoccupations such as vague gastrointestinal disorders, and nutritional changes are widely reported. Concern about his adequacy as a provider and protector may erode an expectant father's self-esteem. Mood changes, frequently expected in mothers, also occur in fathers: "Even before the birth of his child, the father's life, his body, and his mind are busy making ready in ways of which he may only have a passing awareness (34)." Birth preparation and perinatal classes may be helpful and supportive to both mothers and fathers in promoting a sense of mutual commitment and in explaining the universal pleasures and fears during the pregnancy and birth phase. Both mothers and fathers have complex mental images of their children (often crystallized with the help of well pixilated ultrasound images) long before the child sees the light of day.

Few human experiences rival birth itself, with first contact feeling so powerful for both mothers and fathers. Attachment and bonding research has clearly articulated the importance of the parent–infant haptic involvement in the hours and days following birth. Fathers who are present at the birth are more verbal about their babies, more accurate in describing them, and are more intimately attached to them at follow-up (35).

The newborn's job is no less salient—though more complex neurobiologically—than that of the parents (69). The neonate must first stabilize and regulate themselves neurobiologically in order to perceive and respond to events in the external world by processing sensory, vestibular, and human interaction (70). Next, newborns must use their repertoire of skills and intrinsic reflexes to try to elicit sensitive nurturing experiences from the human world, which then facilitates their entering the dynamic, reciprocating intimacies of relating pleasurably to, and accurately with, their caregivers (71).

Finally, infants must communicate in a meaningful, intimate way so that they will be stimulated, fed, entertained, and cared for physically. Both mothers and fathers, whether or not they have had prior experience, learn by on-the-job training to read, as well as anticipate, their infant's signals. Empathic connections and the capacity to comfort, soothe, woo, distract, and entertain are tasks common to both sensitive mothering and fathering. Qualitative differences are present, however, in the idiosyncratic ways in which mothers and fathers respond (35). Mothers tend to

respond to their babies on a more intimate scale, facilitating fine motor development and affective differentiation. Fathers tend to be more activating and gross-motor involved. Nevertheless, as shown by Parke, fathers are able to feed and comfort their babies as effectively and efficiently, although somewhat differently stylistically, as their partners (all couples in the study were married) (72).

Infants also appear interested in, and responsive to, the differences between paternal and maternal interactive styles (73). Yogman (74) noted that by the time infants were 8 weeks old, they were responding differentially to their fathers and mothers. At 8 weeks, infants hunched their shoulders and lifted their eyebrows when their fathers appeared in their visual field. The same infants, when they saw or heard their mother's approach, seemed to expect more routine functional handling, such as feeding or diapering and became settled with relaxed shoulders, lowered eyebrows, and more regular breathing rather than become animated.

The involvement in the first year of life of two caring and competent adults appears to have a positive effect on overall cognitive development. Pedersen et al. (75) found that the more actively involved a 6-month-old had been with his or her father, the higher the infant's scores on the Bailey test of mental and motor development. Parke (72), in examining children over the first 8 weeks of life, found that the more fathers were involved in everyday, repetitive aspects of care, such as bathing, feeding, dressing, and diapering, the more socially responsive the infants were.

It is in the mutual pleasures of this early experience that the adults, who have now moved up a generation and become caretakers to the younger generation, feel their own personal development frequently propelled forward to new levels of empathic —even altruistic—connections, not only with their children but also with other important objects in their lives.

Given these important health-promoting interactions in the first year of life, we are wise to take seriously the potential effects on the infant of time-sensitive adult vulnerabilities during this era, such as postpartum depression. The prevalence of maternal postpartum depression and its potentially negative effects, if untreated, on the infant is well-known. Recent research draws our attention to the unexpectedly high incidence of paternal postpartum depression in fathers, once researchers began to investigate it (76). Untreated, this can further complicate comorbidity in the mother and potentially further threaten the infant's well-being in the first year (77).

Toddlerhood and Individuation within the Family

The child's astounding increase in mental and physical resources propels him or her out of the less differentiated omnipotence of the first year of life into a much more social context, in which new skills permit more active participation and shaping of the need-satisfying environment. The development of language, increasing

sophistication in cognitive structures, mastery over motility and sphincters, and the incorporation of gender awareness all prepare the child for the complex sequences of the vital separation–individuation process (78). Parents are alternately challenged through intense clinging and contentious interchange, giving this era *ambivalence* as its marquee. Aggression, caretaking, affection, anger, and sensuous intimacy are now part of the toddler's repertoire (49). This makes limit setting a vital companion to the toddler's adventurous experimentation with challenging, aggressive, and seductive behaviors. The parent is wise to be led by, rather than attempt to lead the toddler (79). Fathering styles are more differentiated from mothering styles of interaction, with fathers initiating more rough-and-tumble, unpredictable, physical, and stimulating forms of play. Biller and Meredith noted that mothers tended to engage in more conventional, toy-mediated play, picking up their children to engage in caretaking and nurturing activities more often than fathers (80).

The child's increased level of mastery over the internal environment leaves more energy available to explore the boundaries of the external environment, giving separation tasks more salience during this era. Adjustments to the toddler's new, if clumsy, drive for autonomy are necessary to avoid prolonging the child's functional dependency. Because separation from the mother sometimes is the fuel for the sleep disturbances that are common during the second year of life, the father can help decrease the virulence of nighttime disruption by being the one who soothes and settles the child. This spares the child from yet another separation from the mother, while also helping the child feel safe and secure.

Clearly, the child's unique temperament and style interact with parental values and experience with regard to personal autonomy, separateness from family of origin, and impulse and bodily control. The unique contributions of the father during these years have been increasingly recognized as important to the success of this developmental era (81), and need to become a more routine part of the health professionals approach to, and their systems and routines of care of, children from early on (82).

The Preschooler

The preschool child's appropriate use of personal pronouns, ability to say "no," and increasingly adaptive capacities all draw the family as a whole further into this new domain characterized by three-party, rather than two-party, relationships. Curiosity, assertiveness, and the capacity to begin to delay gratification help the child regulate and moderate intense instinctual impulses and affects. Cognitive growth, meanwhile, assists the child in learning and remembering what the important objects in his or her life will or will not tolerate. Appropriate, predictable limit setting, counting to 10, and humor play important roles in helping both the child and parent withstand the heavy weather of strong, rivalrous feelings. By now, parents are able to yield most

control over bodily functions to the child, relinquishing him or her as a physical possession, and become more admiring and encouraging of his or her attributes as a separate, human being who is becoming aware of the benefits of the delay of gratification. During these preschool years, fathers interact with their children mainly through play, limit-setting, and productivity. Through role modeling, the father provides opportunities for children of both sexes to build increasingly positive self-esteem (83).

We are now aware that maternal and paternal styles of attachment behavior differ from one another; maternal attachment behavior is designed to provide comfort and security to the young during periods of stress and distress. Paternal attachment provides security during monitored controlled excitement through sensitive and challenging support "*when child's exploratory system is aroused*" (84). Such dynamic distinctions show the benefit of positive and consistent involvement of both parents in supporting the separation/individuation tasks faced by the child during this particular era.

The press of such developmental needs during this period, highlighted in research, shows us a critical relationship between marital satisfaction and parental involvement. Marital satisfaction can be at its lowest ebb during the childbearing years (85). Waldron and Routh (86) note that marital satisfaction follows a U-shaped graph, with higher levels of marital comfort before children are born and again after they leave home. Frequently, children place such significant demands on the couple that there is little energy left to fuel, let alone sustain, the marital relationship, though it is not suggested that children destroy marriages. Rapoport et al. (87) report that marriage often is experienced by fathers as better than by mothers during this nadir of marital satisfaction because it is mothers who usually have more negative experiences with their children, feel more isolated, and are more vulnerable to psychosomatic stress ailments, including fatigue. Although the discrepancies between maternal and paternal experience can be problematic, including occasional envy and jealousy on the part of the parent who is having the more difficult and challenging time with the preschool child, the long-term effects of having both parents involved intimately during this phase are strongly positive. Awareness of the positive effects of co-parenting on the parental relationship seems to be on the increase, as documented by current surveys of parental wishes and expectations (28).

One of the more dramatic findings in the father–infant care research is the relationship between early involvement and subsequent sexual abuse. If a man is involved in the physical care of his child before the age of 3 years, there is a dramatic drop in the probability that man will be involved later on in life with sexual abuse of his own or anyone else's children (88).

School Age and Family Unity

The timely differentiation of the child–parent relationship from interdependent dyad to more intergenerational autonomy allows the child to make powerful psychological investments in nonparental adults. An unexpected sequela of this change is the potential for the first disillusionment in one's parents. Just as the child's body is relinquished from parental control, so is the child's mind. The family now helps the child separate for most of his or her waking hours to attend school and confront social and cognitive challenges. Interest grows exponentially in relating to other children and adults, as well as for learning and problem-solving. The integration of family and tradition, as guided by societal mythology, serves as the hallmark of this period of development. It often becomes easier for a family to spend prolonged, uninterrupted segments of time with one another for community or neighborhood activities or projects, and simple travel or leisure activities. Girls may have only one or two friends they would call "best," whereas boys may name six or seven friends, who usually turn out to be somewhat more casual acquaintances with whom they "do things … hang out." The opportunity for shared activities and mastery experiences with adults of the same sex is extremely important in terms of the solidification of gender role behavior and gender identity itself. During the school-age period, a father may serve as a confidant, a pal, even a friend, or teacher (89). Father absence, however (90), leads teachers to rate both boys and girls as more aggressive relative to mother–father families. Especially poignant was the finding that the protective factors for mother–father families were less apparent among low-income families.

Adolescence and Generational Redefinition

Families of adolescents craft boundaries that are qualitatively different from families with younger children. These boundaries assist the children in managing their own impulses because parents no longer have the unquestioned authority they once enjoyed. The boundaries between the family and the outside world must become more permeable, hence the normal careening and ambivalence between independence and dependence. The adolescent's sense of self is beginning to be consolidated and shaped by the search for pleasure and purpose with goals and tasks that can stretch far into the future and at other times be more immediate and impulse-driven. They are intensely interested in and preoccupied by their constantly changing bodies and moods. Meanwhile, accepted family values such as "do unto others as you would have them do unto you" [beliefs more typical of middle childhood] are subjected to greater scrutiny.

Developmental stress does not necessarily doom the family to turmoil during this phase, but profound physical and psychological changes not seen since toddlerhood threaten the previous level of homeostasis. Adolescents notice weaknesses and vulnerabilities in their family, as well as in their own psychological functioning, but these may also be seen as possible points of departure for new adaptive functioning.

Uncertainty about where strengths and weaknesses lie, and intergenerational disagreement about their relevance can lead to disputes. And adolescent observations are notoriously selective; bulimic teenagers and young adults rated their fathers as showing less affection and more control toward them than their nonbulimic siblings, suggesting that the paternal relationship may be a source of nonshared environmental experience associated with bulimia (91).

Adolescence can be a period of significant stress in the family because both the adolescents and their parents are often experiencing physiologic and mental changes simultaneously. Both generations may be scrutinizing their primary relationships anew and questioning their value and trustworthiness. Just as adolescents are beginning to make choices regarding values and life goals, their parents are often needing to accept that certain of their own cherished goals may never be achieved, becoming preoccupied with the limited time left in their lives.

As adolescents pull further away from the nurturing domain by taking a job or starting college, the parental response can be one of either pride in their child's capacity to cope with life's new challenges, or sadness over what appears to be their increasing absence from family life. An adolescent's need to extract his or her autonomy from the parental nurturing domain can be a strong challenge to a family's homeostatic balance.

THE LATTER STAGES

Young adulthood emancipation, the marriage of offspring (the "middle family"), and, finally, aging and senescence are the last three phases of family development. The kind of influence parents now have on their children is largely encompassed by their ability to provide resources, availability for discussion and advice and by bearing witness to their children's integrity, while being careful to support their own autonomy. Grandchildren may come next, providing an opportunity for rejuvenation of spirit and body (and hints of immortality). The potential relaxations of retirement, the consolidation of the family around a patriarch or matriarch, and finally, the privileges and honor of the emerita/emeritus define the tableau of the senior family era.

The developmental tasks faced by the child and the child's caregivers are the same whether the structure of the family is nuclear or not, same-sex or heterosexual. The energy and resources, both emotional and physical, to attend to those tasks are strongly influenced, however, by a particular family's resources, limits, and flexibility. Adoptive, single-parent, foster, and recombined family groupings are all subject to the same leadership, boundary, affectivity, communicative, and task and goal requirements. The issues of attachment, separation, emancipation, loss, and response to change are largely the same. Each exerts its own particular spin on normal development, but none is doomed to trouble by dint of family structure alone.

Adoptive families often do not have the same biologic preparation time, but given support, and some measure of good fortune, they usually follow a similar psychological preparation sequence. The separate biologic parents' narrative can be integrated into the family's mental history of itself over time, ensuring continuity to the child's narrative of how he or she became themselves. Single-parent families, whether male- or female-headed, face depletion and isolation early and often and work best when social and medical support systems are available early and are flexible enough to supplement parental and child needs.

Recombined and reconstituted families—when a divorced, widowed, or never-married single parent forms a new household with a new partner who may or may not be a parent—are also increasing. Depending on the mode of single parenthood (death, divorce, abandonment), the new parent may be seen as a threat, or solution, to intimacy between parent and child. Rivalry and jealousy frequently stimulate guilt and anxiety. Interestingly, Black and Pedro-Carroll (92) have shown that the effects of interparental conflict on the psychological well-being of children were mediated more by the overall quality of parent–child relationships than by inter-adult conflict itself. Stepparents frequently are in risk situations, being tested by their "new" children while feeling special loyalty to their "old" children, and simultaneously trying to grow and sustain a new spousal relationship. Time (measured in years), patience, and liberal, frequent communication (sometimes new to everyone as a process) plus permission to co-parent are all essential. Society's myths are of little help; *stepmother* in English conjures up Cinderella's stepmother, and stepfather in Spanish is *padrastro,* which also can mean hangnail. On a smaller scale, all families face similar issues because families are always reconstituting biologically and psychologically. Because of the relentless push of developmental and maturational forces in the individuals of our species, like the river, one can never step into one family in the same place twice.

IN SUMMARY

As we review these developmental trajectories for families, we note the parallel processes at work in the developmental trajectory of the career of the child psychiatrist. How is the art of the practice itself woven over time into the child psychiatrist's personal growth and development? Their own personal context shapes their practice, and their personal attitude toward it, in countless ways. For example, they do or do not become parents themselves, struggle with the same universal doubts, joys, slings, and arrows of either path. I have heard my students wish aloud that they could revise some old piece of advice given or judgment made through the lens of their own personal experience of parenting or not. On the other hand, those who do have children may at times carry the burden of self-doubt as a useless "expert" when they have no idea about how to help their own distressed offspring or

despairing spouse manage some interpersonal or intrapsychic skirmish.

Child psychiatrists struggle with their own health issues, emotional and physical, suffer personal losses, and experience their own 15 minutes of fame, or not, all the while trying to listen with mustered patience, during times when they are feeling unheard themselves. This is one of the compelling reasons that vigilance, supervision, and collegial support throughout one's professional life should be the rule, not the exception.

Such vigilance is especially germane if the clinician holds to the standard, "treat others as you would have them treat you." Desirable as this standard may be, it occasions personal depletion at a rapid clip. A lifelong trajectory of repletion through reflective supervision, real continuing education [not simply CMEs], restorative play (mental and physical), and diversion will protect and preserve that "knack" for listening for meaning in what matters to our patients and their families.

Over time I have grown less judgmental, more patient, and I hope more reflective, effective, and efficient with age. I am freer with my doubts, humor, and compassion, and more grateful for what I have learned from my patients' shared experiences in our work together. I assume from the beginning that my patients—child and family—are doing the best they can, regardless of how troubled the results of those efforts to date may at first appear.

At the same time, I feel more demanding of myself and my patients, trusting our skills and creativities more than I did at the beginning of my career, when I thought life might somehow be more perfectible. Innovations seem to arise in more and more cases, partly as a function of the extraordinary pace of science's advance in our field. In fact, as I reflect on the beginning of my career, I wonder if we as a medical specialty got so good at asking questions because there were so few answers; this may be less the case today with the arrival of each new online journal. It is hard to imagine a medical specialty with a broader intellectual horizon than ours (a strong recruitment talking point whenever I get the chance).

That is precisely why I am simultaneously enthusiastic and concerned about our ongoing preoccupation with evidence-based medicine. On one hand, it can upgrade the quality of evidence that we use and generate, and upon which we rely to make diagnoses and develop treatment plans. On the other hand, "evidence" for its own sake or in isolation falls short of helping the clinician "do the right thing" because the patient's needs are embedded in the complex context of their culture-specific, value-laden, intergenerational "system" of beliefs and hopes [as are the clinicians!]. Few have said it better than Jeree Pawl (93):

> We learn over time that everything we think we know is a hypothesis; that we have ideas, but that we don't have truth. We learn that those [patients] with whom we work have all of the information we need, and that this is what we will work with. When we know this, our attitude conveys it; and the child and family sense

themselves as sources, not objects. In this context, they become aware of a mutual effort; they do not feel weighed, measured, or judged. They feel listened to, seen and appreciated.

If the reader is interested in such support in a narrative form, I commend my mentor, Kenneth Robson's brief and wonderful book, «The Children's Hour; A life in child psychiatry (94)»

CHAPTER 1.2 ■ ETHICS

ADRIAN SONDHEIMER

The assertion that Mel Brooks is arguably the finest, and paradoxically the longest-living (traversing numerous cultures and eras over many centuries) American Jewish philosopher of the second half of the 20th century (1), might be open to disagreement by some. It is offered as an opinion, quite possibly not universally shared. Further, Mr. Brooks' assertion that "it is good to be the king" (2), while often a truism due to its emphasis on noblesse oblige (though others might disagree, viz. Kings Charles I, Louis XVI, Conraden of Italy, who all literally lost their heads while in office), speaks to the benefits of privilege by virtue of position, the exact opposite of what other philosophers would generally agree to be universal values that apply to all human beings. Such musings, encompassing history, human behaviors, and senses of humility (and humor) or the lack of them, lead naturally to a discussion of ethics, a branch of moral philosophy the study of which also transcends millennia. Simply put, such study attempts to determine the rightness and wrongness of human behaviors. The Golden Rule and the Ten Commandments are commonly known efforts, in the near Eastern and Western worlds, to create such ethically universal rules, though they may often be limited by parochial concerns.

The English word *ethics* derives from the Greek *etikos,* commonly understood to refer to "character," as used in the judgment of an individual's honesty, virtue, trustworthiness, and personal conduct. Ethical thinking thus strives to define norms or standards of desirable human behaviors that would be applicable in all circumstances and are not, by contrast, situation dependent. These standards are pertinent independent of the professional discipline to which they might be applied, as in *medical* (as distinct from, e.g., legal, business or educational) *ethics.* In other words, universal ethical principles do not change because they are applied specifically to medical practice, while medicine as a discipline is required to work with these principles by applying them to its practice. Psychiatry is a branch of medicine, child and adolescent psychiatry (CAP) is a subspecialty of general psychiatry, and, it follows, to do good work, ethical thought must be applied to CAP practice.

CODES OF ETHICS

For millennia, societies have designated specified individuals within their communities as professional healers who might be known, for example, as shamans, witches, physicians, and/or doctors. The communities have always expected their healers to have mastery of the knowledge of their profession and to pursue, as their primary interest and obligation, the betterment of the welfare of the individuals

seeking help from these professionals. Consequently, over all these years, societies have created numerous codes designed to guide proper practice by their healers. Executed by the healers themselves or in concert with other informed members, the codes have derived from the moral, philosophic, and religious ideas embedded in the community, and they served as the bases for standards of conduct the communities expected of their practitioners (3). Almost invariably, these medical codes touched upon several or more of the following topics: respect for human life; provision of benefit and avoidance of harm; the need for personal virtue; acknowledgement of duty to, and responsibility for, the patient; financial considerations; diagnostic methodologies; therapeutic choices; confidentiality of patient–physician communications; prohibition of sexual contact with patients; and, punishment or sanctions for poor technical performance.

ETHICAL PRINCIPLES

The knowledge and attitudes of these societies would undoubtedly change over time, leading to changes in what might be considered, at any particular point in time, right or wrong behaviors. However, certain principles evolved that were considered to be immutable. These have recurred as constants in emerging and evolving codes. Thus, ***beneficence***, within the medical context, refers to the obligation to contribute to the health and welfare of patients and to further their legitimate interests. Its converse, ***nonmaleficence,*** cautions against the infliction of evil or harm. The cardinal medical maxim, *primum non nocere* (i.e., above all, do no harm), appears in the Hippocratic Oath, a commonly cited and utilized Western medical code established ca. 400 BC. This maxim is directly based on the underlying ethical principle of nonmaleficence. It should be noted, though, that at the time of its initial promulgation, a major intention, when considering this principle, was to warn against the performance of surgery by most current physicians. ***Autonomy*** refers to the notion that individuals are due, by inherent right, freedom of action and choice, provided that such choices do not infringe on the rights of others. Within the medical context autonomy implies the patient's right to make decisions for oneself, even in the face of opposition by others, for example, the physician. ***Justice*** implies fairness. This principle demands that all individuals are to be treated equally and fairly, unless the differences between them rationally justify differential treatment. Additional universal principles have been proposed. Thus, for example, ***fidelity***, which encompasses the obligation to be faithful and loyal to persons and their needs, and ***veracity***, emphasizing the obligation of truth-telling, inclusive of misleadings consequent to the omissions of facts. In any case, these principles stand as unique bases, covering proper practitioner conduct (4). They are considered universalizable, that is, applicable in all conceivable circumstances, and overriding, that is, taking precedence over personal and group values.

ETHICAL REASONING PROCESS

When faced with ethical dilemmas, whether in the clinical, educational, administrative, or research spheres, the fundamental ethical principles are employed in a reasoning process designed to enable practitioners to arrive at least damaging resolutions via an objective risk–benefit analysis. Described simply, the process involves the initial encounter with a problem, followed by the recognition of underlying ethical conflicts. The practitioners should rapidly identify their immediate affective responses and inclinations for action in order to then set them aside, allowing the practitioners instead time to reflect. Doing so provides the opportunity to obtain a sense of prevalent current practice concerning the matter and greater cognizance of one's own value systems and their derivations, to incorporate the views of others involved in the subject of concern and, finally, to employ the previously cited principles which, not infrequently, may conflict with each other. ***To illustrate:*** the Hippocratic Oath, emphasizing the avoidance of harm, meant, in its day, "do not do surgery." In that era's absence of both anesthesia and sterile technique surgery was commonly an exercise in maleficence, despite the physician's beneficent intentions. Thus, in the ethical reasoning process, one principle will predominate over another. However, with changes over time in medical knowledge and expertise in provision of care, reversals of these priorities can and should occur, and they have.

HISTORY AND CHILDREN

Societies' desires for healers go back millennia. While initial writings focused exclusively on somatic concerns, comments about mental disturbance first appeared in works by Hippocrates in Greece and, several centuries later, Galen in Rome. The etiologies underlying manifestations of mental disturbance and its proposed treatments were debated in those days and have been ever since. Of note, however, all of these writings, until relatively recently, centered exclusively on adults and their needs. Children, by contrast, were generally viewed in society as objects, owned by their parents. In exchange for housing and food, the children were expected to provide service upon achievement of physical capability. Notions of formal education of children did not emerge until the 17th century, and, at that time, their applications were limited to the privileged classes (5). Gradually changing impressions, and the development of new technologies, led to an increase in educational opportunities for wider groups of children and of perceptions of children as developing individuals with their own rights, rather than as "little adults." Consequent to these changing perspectives, pediatrics first emerged as a medical

specialty in the last decades of the 19th century. During the following century, various agencies were created and legal precedents established, in both the USA and England, designed to aid and protect children, including, for example, the first juvenile courts, Federal Children's Bureau, U.S. Supreme Court decision In re: Gault, and Britain's Guardianship of Infants' Act.

These evolutionary societal changes were paralleled in medical and psychiatric practice. In the USA, 3 years prior to the establishment of the American Medical Association in 1847, 13 superintendents of American "insane asylums" banded together to form an organization that served as the foundation, eight decades later, for the formation of the American Psychiatric Association. That organization, in turn, created training standards for its trainees. Mirroring the public's newfound concerns for youngsters, a group of psychiatrists and other fellow professionals, with shared interests in children, created the American Academy of Child Psychiatry (AACP) in 1953. The AACP formulated training standards for child psychiatrists, and created its first Code of Ethics in 1980 (6). That code has since undergone several revisions to bring it in line with current knowledge and attitudes (7). Education in ethics is mandated by CAP training requirements as the specialty's residents are inevitably exposed to varieties of ethical dilemmas. These dilemmas serve to sensitize the trainees to conflicts they will undoubtedly face during the rest of their careers. The AACAP Code of Ethics thus serves as a valuable potential resource, in perpetuity, to CAPs that are destined, periodically, to encounter perplexing ethical problems. International codes, discussed later, hold the same importance.

CHILDREN, ETHICS AND LAW

Children are not little adults. They developmentally mature over time, in the physiological, cognitive, language and affective spheres, as well as in their social relationships with others. As a group, children are best not viewed as a single unit. Rather, they must be differentiated at distinct developmental stages, beginning with infancy and advancing through the preschool, school-age, adolescent, and transitional-age youth phases. Concomitantly, the application of ethical reasoning must attend to the individual child's developmental attainments within his or her specific phase. ***To illustrate***: A 2½- and a 17-year old may refuse a recommended and sensible medical intervention. As their cognitive capacities differ greatly from each other, given their ages, it is much more likely that the practitioner will respect the autonomy rights due the adolescent in contrast to those of the toddler. Similarly, the clinician is less likely to respect the autonomy of the 15-year old suicidal adolescent when compared to that of her relatively mentally healthy peer.

Of note, with the exception of the transitional-age youth, a child or adolescent commonly does not possess the legal right to refuse a medical intervention. Legal consent to proposed care resides with the youngster's adult guardian, most commonly

a parent. The contrast of the law with ethical considerations is important, and the CAP should not confuse one with the other. To that end, ethical codes embody broad standards of preferred conduct. Ethical reasoning, employing fundamental principles, similarly serves as a guide to making moral choices. The law, by contrast, tends to be definitive, with little elasticity. CAP practitioners are ethically obligated to be aware of relevant laws, but the ethical choices that are made might, depending on the dilemma, conflict or agree with the law as written. For example, laws mandating distant biological relatives as the primary options to provide guardianship for neglected or abused children might conflict with the emotional needs of children who have experienced valued long-term "temporary" care with biologically unrelated foster parents.

ETHICAL REASONING AND CHILD-RELATED CONCERNS

Ethical considerations regarding children differ from those affecting adults in three major ways. As previously noted, children live in a state of developmental flux. With each child, the degree of developmental attainment must be determined, while acknowledging that the youngster has not matured to the level at which adult rights are accorded. Second, while children's opinions and desires deserve respect, it falls to adult guardians to make definitive choices about the youngsters' care, and not to the children themselves. Clearly, the child's and guardian's views may coincide or conflict. When the latter occurs, practitioners face dilemmas. A common question ensues—to whom does the practitioner owe fidelity? And third, the nature of child care often involves multiple parties. These may include guardians, parents, school systems, physicians, social agencies, courts, and other interested caregivers. Information about the child is often needed, requested, and exchanged. The nature and degree of those exchanges, as well as the navigation of permissions for the information transmission, commonly raise concerns about the information content, intents of the recipients, and the extent to which the child's privacy is maintained.

Context affects ethical reasoning as well. Well-endowed parents, communities, and countries are capable of providing more assets for their children than those with limitations on available resources. Thus, recommendations for special education, medications, or legal assistance might frequently be indicated, but their provision would be impossible in specific contexts. To ignore those realities but nevertheless make such recommendations in impoverished settings, thus heightening uncalled-for hopes, would ultimately negatively impact the intended recipients, producing maleficent impact. Relatedly, indicated resources allotted to one individual could render such supplies unavailable for another, equally needy, child. These considerations commonly raise the issue of balancing the needs of the individual with those of the larger society (8).

Cultural considerations may also affect ethical reasoning. One society might

encourage and support children who challenge the status quo while another urges unquestioned obedience to elders. One culture might support unrestrained access to care while another defunds or stigmatizes it. While practitioners must always consider contextual and cultural factors in their deliberations, two criteria, as well as the four primary ethical principles, demand universal applicability in the ethical reasoning process, independent of culture and context. First is the assurance that children's safety must have priority over all other considerations. Second is the requirement that practitioners employ deep reflection and careful and rigorous thought when they attempt to resolve ethical problems.

ETHICAL CONCERNS ABOUT CHILDREN AND CARE

Children brought to psychiatric attention require thorough evaluations. When the evaluations are completed, recommendations are made and commonly implemented. Reports are written and documents are created, transmitted, and stored. Stored electronically, these documents have long lives. They have the potential to affect the child's care for years, and practitioners are ethically bound to use caution in their wording and dissemination. Thus, CAPs are ethically obliged to bear children's short- and long-term interests constantly in mind. If it is determined, in the course of an evaluation, that a child lacks competent adult supports, the CAP has the additional ethical responsibility to act as advocate on the child's behalf. *Advocacy* as an obligation differentiates CAPs from professionals who provide care to patients who have reached the age of majority and who, therefore, bear full adult responsibilities for themselves (9).

ADVOCACY

Work with children invariably involves the children's caretakers. Provision of *beneficence* for the child requires the CAP to be aware of the child and the pertinent guardians, and the importance of the latter to the former. However, when push comes to shove, the CAP must prioritize the needs of the child over familial, agency, or societal counterpressures. Notably, the CAP as forensic evaluator is sometimes cited as an exception to this general rule, as that professional role has the primary obligation of rendering sound scientific opinion to the entity requesting the information. Even in those situations, however, the CAP is mandated to actively consider the full range of needs of the child (ibid. 7 – Principle II). *Nonmaleficence* refers to the obvious expectation of CAPs that they will not engage in harmful or exploitative behaviors toward children under their care. A stipulated corollary is the expectation that the CAP will act to prevent harmful or exploitative acts, directed by others, at the child receiving professional attention. Insofar as the *justice* principle

urges the CAP to continuously consider how care might be improved and how relevant injustices might be countered, these three principles (beneficence, nonmaleficence, and justice) combine to promote a major CAP responsibility, that of *advocacy* for the minor. Periodically, a child or children may lack adults who act in their best interests, be they guardians, social agencies, or legal representatives. It becomes the ethical responsibility of CAPs, at those times, to advocate for the minors' needs, as individuals and as a group, as the children themselves are deemed cognitively and politically incapable of competently defending their interests.

DOCTOR–PATIENT RELATIONSHIP; ASSENT AND CONSENT

Basic to physician–patient interactions is the existence of mutual *trust.* When working with children, the CAP–patient relationship is actually created between the CAP and two entities—the child and the guardians. Both of the latter have interests in the process, and it is with both entities that trust ideally is established. The relationship begins when the guardians, child, and physician first meet. While the physician–patient relationship is a legal one, and violation of that relationship could lead to legal sanctions against the professional, the primary basis for the relationship is the faith invested by the child in the physician. That patient has the complete right to expect that his or her best interests will always be the primary guide to recommended interventions and that the healer will avoid pursuing goals that primarily benefit the physician. ***To illustrate:*** "You told me that if I threaten to harm others or myself you'd tell my parents; all the other stuff is between you and me. Well, during the last few weeks I've done ecstasy twice. I don't want them to know —you going to tell them?" Response with a simple yes or no, accompanied by the CAP's justifications, quickly obscures the primary issue—can the adolescent trust the CAP to think through the matter carefully, with the patient and independently, and ultimately advise a course of action that does not undermine the faith and confidence of the patient in the physician? That element is the one most crucial to the outcome.

Except in cases of true emergencies, when safety of the child becomes the prime consideration, it falls to the adults to provide ***consent*** for the medical procedures which follow, be they the initiations of evaluations, research studies, or continuations of treatment. Children below age 18 cannot legally consent to these procedures though they may request, ***assent*** to, or ***dissent*** from, them (10). Minors, in general, are not considered legally endowed with *competence,* that is, the attribute ascribed to adults of the capacity to appreciate the contexts and effects of their behaviors. Legal exceptions for minors are made for emancipated adolescents and in some instances surrounding a minor's pregnancy.

Consent should always be informed, that is, all the parties, including the minor, need to know the nature of a diagnosed condition and the risks or benefits to be

derived from accepting or forgoing treatment. Relatedly, coercion of the parties to comply with proposed care should generally be avoided. In the event of interparental dissent, as could occur with, for example, divorced parents, one must determine which parent(s) have legal medical decision-making rights concerning the child. In any case, independent of age, the children's desires or refusals are always to be acknowledged, and their assent should be obtained free from coercion. The degree to which the minor's wishes are seriously considered, however, will depend on the individual child's age and cognitive maturity as well as the clinical circumstances.

Assent is always preferred and desirable as the child is more likely to cooperate with proffered care; communication between all the pertinent parties is facilitated; mutual respect is better maintained; and the child experiences a greater sense of control of the process. On the other hand, on occasion treatment can, and sometimes must, be provided to children in the face of their dissent. Safety considerations should trump the wishes of suicidal youngsters who oppose hospitalization, as should mature adult cognitions prevail over the squalling tantruming of the preschooler who, for example, might dissent from entering a classroom. Thus, respect for autonomous dissent also requires sensible limits.

AGENCY

The CAP is commonly exposed to multiple stakeholders when dealing with problematic cases. While aware of the need to serve as the child's advocate other interested parties, including guardians, regulatory entities, social agencies, schools, faculty hierarchies, health insurance companies, and sponsors of research, may apply pressures, based on economic or other concerns, and demand the CAP's attention.

To illustrate: A second-year psychiatry resident, performing a 3-month CAP rotation, informs the faculty CAP supervisor that she intends to call the state's child protective services agency (CPS) to report abuse by the foster parent of a 10-year old girl in temporary care. The girl mentioned, in an outpatient treatment session, that the parent had hit her thrice on her legs with a broom handle as punishment for returning home half an hour late from school. This physical reprimand left faint bruise marks on her skin. The resident noted that the girl had previously resided, with rapid turnover, in three foster homes, had lived with the current guardian for the past 3/4 year, the guardian and the girl had developed a warm mutual relationship, and this temporary foster parent had recently spoken of her intention to seek permanent adoption of the girl.

For whom is the CAP supervisor an agent? Is the faculty CAP's major obligation to provide quality education for the resident? As safety is always the primary consideration, the CAP must consider whether the child is at risk for near- or longer-term harm. Would the child benefit from removal to another foster care placement or could the current situation be maintained, salvaged, and improved? Would it be

possible to accomplish the latter if CPS were to be notified and subsequently intervened? Might such a move and intervention wreck the possibility of adoption, by the seemingly loving temporary foster parent, from going forward? Might contact with CPS prevent future abuses of the girl? And what of the statutory mandate to report abuse to the designated authorities? What might the impact be on a trainee who observes a faculty member following through on this reportage obligation, possibly followed by damage to, or the severance of, the girl's relationship with her foster parents? Or, to the contrary, of receiving advice from the attending, due to this concern, that they should abstain from reporting, thus encouraging a trainee's violation of the law? The CAP must consider all of these possibilities and the competing interests of these parties. Acceding to the demands or expectations of some will undoubtedly alienate others. But, after weighing these competing interests, the CAP must ultimately decide on an approach that will keep the child's best interests as paramount. Thus, despite feeling beholden as an agent with partial obligations to multiple entities, the fundamental choice must devolve to that of advocate for the most vulnerable entity, the child. In addition, in the course of intervention, the CAP ideally engenders discussion with, and possibly between, the involved parties. Acting thus as facilitator, the CAP propagates potentially greater "buy-in" and collaboration from all those affected by a case, even as their cultures and views may clash with each other. But, in the end, with or without discussion, the CAP's obligation remains to act as the child's agent.

CONFIDENTIALITY

Confidentiality of communications between patient and physician is a bedrock for the development of mutual trust between the two. The patient has the assurance that what has been revealed to the CAP remains between them, not to be divulged without the patient's permission, with an exception provided in the event the patient indicates imminent danger to self or others. Work with young children does not ordinarily pose a problem as they often expect, and are even desirous of, communication of their thoughts by the physician to their guardians. However, not infrequently, adolescents and transitional age youth will test, via provocative communications, the CAP's capacity to live silently with ambiguity and worry.

As a separate matter, interactions between the CAP and children's guardians are, not infrequently, complicating factors. A good relationship between the CAP and the guardians is commonly crucial to the continued treatment of the child. The guardians usually want, and are entitled, to know about matters relating to their child, and the CAP must provide them with pertinent information without violation of the patient's confidentiality concerns.

The phases of children's growth coincide with gradual development of prefrontal cortical neuronal architecture. Impulsive behaviors and inadequate self-control are

associated consequences of immature brain development observed in youth (11). Thus, with regularity, CAPs are informed by their adolescent and younger transitional age youth patients of, for example, illicit drug ownership and use, sexual activity, cessation of prescribed medication use, intemperate physical and verbal outbursts, and contemplation of or engagement in behaviors that skirt or violate the law. If the CAP were to discuss these matters with the youngsters' guardians it is likely that, after an experience of initial upset, the adults would be appreciative and seek to remedy the situation. However, if the information were conveyed without prior notice to the youths, or without their assent, the patients would likely feel alienated and quite possibly terminate care.

Approaching cases with a family-centered approach, where possible, manages to contain many of the concerns around confidentiality (12). This method, described to the participants at the outset, reconciles the guardians' desires for information with the patient's need for confidentiality. The concept of confidentiality and its breadth and limits are briefly mentioned but, much more importantly, the desirability of cross-communication, transparency, and the utility of trust in the physician to keep the best interests of the child foremost, while including employment of judicious exchange of information among all parties, is emphasized.

Limits on confidentiality, in professional contexts other than the therapeutic setting, must be acknowledged. Forensic CAP examiners must inform the child under evaluation, and the child's guardians, that none of the material obtained during the course of the interviews has confidentiality protections, and that the obtained information will be shared with the requesting parties. On the other hand, all patient-related notes, in addition to those taken during forensic evaluations, should contain no extraneous data, and care must always be taken to ensure that exposure of the written material is limited to previously designated and approved pertinent recipients. Research subjects are entitled to anonymity, without identifiable attributes, while their data is grouped together with that of other subjects in a cohort. Not uncommonly, clinicians, CAP trainees, and faculty will orally present or publish material centering on patient cases. It is incumbent on these presenters and authors to disguise inconsequential descriptive attributes that could contribute to the identification of specific patients by others. In addition, it is preferable to obtain permission from a patient (or the guardian, in the instance of a minor) in order to publish material descriptive of a child when significant disguise would result in the distortion of important and germane data. This is all the more true for visual material, itself difficult to disguise, and therefore requiring assent from the minor and consent from the guardian.

ASSESSMENT, DIAGNOSIS, AND TREATMENT

Competent assessments should result in accurate diagnoses followed by, when

indicated, appropriate treatments. To what extent, however, might psychiatrically evaluated children subsequently be stigmatized by their diagnosis? How verifiable are the proposed diagnoses, who is performing the diagnostic process, and with what degree of accuracy? Who has a stake, beyond the child him- or herself, in treatment interventions—that is, to what extent are pressures from family, schools, health insurance companies, and the pharmaceutical industry encouraging, recommending, or demanding specific kinds of interventions? Raising these questions in no way diminishes the value of the diagnostic process, which must underlie treatment interventions. Their answers, however, should indicate whether the sought-after benefit is primarily intended for the patient or, by contrast, for the other parties involved in the clinical picture. Should the latter's interests predominate, a different and new diagnostic process would be ethically required.

The practice of medicine developed over millennia. Progressively, clinical observation, coupled with the incorporation of historical data and later the results of laboratory tests, all of which would be passed through the sieve of comparisons to similar phenomenologic manifestations in other individuals, led to classifications of illness and the desirability of verifiable and reproducible treatment results. This systematic problem-solving approach became the medical model that provided the basis for illness identification and its treatment. This model, itself resting on the scientific method, was incorporated into psychiatry, with the advent of the DSM-III in 1980, in considerably more structured fashion. If, prior to that time, the diagnostic process was conceptualized primarily as established on etiologic theories, it now began to base itself on observed, consensually agreed-to data. This development was a boon to CAP in particular as a significant number of psychiatric disorders clearly present first in children, including those comprising intellectual disabilities and neurodevelopmental disorders. The latter include disturbances of communication, autism spectrum, attention deficit, learning, and motor disorders. Schizophrenia spectrum, bipolar, depression, anxiety, eating, elimination, sleep-wake, gender dysphoria, and conduct disorders usually manifest before the mid 20s and often much earlier. Accurate diagnosis allows for earlier interventions with appropriate specific treatments, preferably sooner rather than later, thus promoting earlier improvement in the child's condition rather than prolongation of the child's distress and suffering (13). Thus, correct diagnosis, followed by scientifically supported integrated medical interventions, ought ordinarily to be an ethically indicated, desirably beneficent, approach.

The treatment armamentarium of CAPs is limited to environmental manipulation, coordination of care, verbal therapies, pharmacologic interventions and, rarely, other somatic approaches. While the knowledge base underlying treatment provision improves and enlarges over time, the multifaceted problems with which children present commonly necessitate use of more than one of the above, if not the majority, of the cited modalities. Ethical treatment requires sound reasoning for the

employment of any of the modalities and, foremost, avoidance of interventions that might prove harmful. Recommendations for inpatient versus outpatient care, residential placement, special versus mainstreamed education, and the choices of specific psychotherapeutic modalities and/or pharmacologic agents all carry potential risks and benefits for the child. These choices may raise questions about third-party influences on, and potential conflicts of interest for, the CAP. Does the CAP receive financial support from any relevant parties to the case, be they the guardians, health insurance providers, schools, or court systems? Are any of these entities suggesting their preferred courses of action to the CAP? Does the CAP, directly or at a distance, benefit from pharmaceutical company largesse? Does referral for psychotherapy to a nonmedical colleague or employee encourage return benefit to the CAP? To what extent, and with what degree of openness, does the CAP address these questions? To what extent does the CAP declare potential conflicts of interest to the patient and family? To what degree does the CAP employ evidence-based knowledge in making therapeutic choices and, when doing so, is informed assent and consent provided? Modes of psychotherapy and pharmaceutics are not inherently good or bad—they both have the potential to improve, maintain, damage, or have no effect on the child's condition. When the above questions are posed and answered honestly and transparently, and a risk/benefit analysis is supplied to the recipient concerning the proposed interventions, treatment can be instituted on a sound ethical basis (14).

For the CAP prescribing or directly providing treatment the ethical imperative is to be knowledgeable, in a comprehensive manner, concerning the range of available therapeutics. Thus, knowledge of medications implies learned awareness of a variety of chemical classes and entities, their indications, benefits, side effects, possible long-term impacts on developing brains and potentials for off-label uses, as well as the necessity to ascertain a patient's current use of "alternative" or "complementary" medicines. The same degree of knowledge holds true for the potential contributions of the psychotherapies. Thus, familiarity with the concepts and the application of psychodynamic, behavioral, familial, and cognitive-behavioral approaches should be expected of the practitioner, whether or not the CAP provides such care directly or refers patients to nonmedical providers for this care. Ineptitude in the provision of verbal therapies holds the potential to be as dangerous to the child as the prescription of inappropriate medication or child placement in an unsuitable facility. In other words, when it comes to providing treatment, the primary commandment is to "above all, do no harm."

RESEARCH

Investigations designed to elucidate disease mechanisms, improve current care, and develop new treatment interventions are imperatives for all medical specialties.

Research is crucial for the development of the field of CAP. As the specialty's focus is on children, however, safety concerns accrue beyond those impacting adult populations and additional safeguards are required in the course of the research efforts in this field.

All research requires the balance of potential benefits versus the risks to the research subjects, and equal risk to benefit ratios are commonly applied to research studies with adults. In contrast to these ratios, United States federal guidelines for research with children require that the benefit to risk ratio be directly favorable to the child participants (15). In thorough and painstaking fashion, proposed research is divided into the categories of "minimal risk," "more than minimal risk, but with the prospect of direct benefit," "more than minimal risk, with no prospect of direct benefit, but likely to yield disorder-relevant knowledge," and "research not otherwise approvable" (16). As might be expected, these categories are often the subject of debates between researchers and oversight bodies, but their thrust is clear—to avoid harm befalling individual child subjects. Secondly, the potential risks and benefits of proposed research requires developmentally appropriate explanation to the child, out of respect to the child's autonomy and geared to the level of the child's cognitive maturation. In addition, both the parents and children must be alerted in advance to distinctions made between studies that offer definite versus possible exposure of the child to a therapeutic agent, for example, in placebo studies. Thus, honest and transparent descriptions of study protocols are required for truly informed assent and consent.

As children are legally minors and therefore unable to provide legal consent, it is required that they assent to their participation in research studies. Legal consent is required from the guardians for the child's participation but, even if that is supplied, a child's dissent is binding, and the child's subsequent nonparticipation in a study would therefore be assumed. A child might experience coercion, from guardians or researchers, to participate in research efforts. Assent provided under such circumstances would be considered obtained in violation of the child's autonomous rights and consequent to undue attempts at influence, and therefore be deemed unethically acquired and nonbinding.

Finally, strong confidentiality safeguards are required, regarding the information obtained from individual children in research studies, related to the filing and later dissemination of collected data. Furthermore, it is ethically required that the aggregated and anonymous data be made public, independent of the nature of the findings and the sources of the funding or other sponsorship of the research efforts, and that the authorial conclusions be accurately based on the study's data-driven results.

EMERGING LOCI OF CONCERN

While fundamental ethical principles remain immutable, they are applied to the analyses of dilemmas that arise in a constantly changing world. A variety of relatively recent scientific advances have brought both benefits and new conundrums. Four areas will each receive brief address—genomics, treatment of psychiatric prodromes, impacts of social media, and potentials for brain enhancement.

GENOMICS

The entire DNA sequence of a human being's chromosomes was first decoded 15 years ago. Prior to that time and since, numerous single gene anomalies were and have been correlated with specific disease expressions. More recently, however, multiple genetic risk factors have been associated with the emergence of psychiatric disorders which are in turn associated with, for example, alterations in calcium-channel signaling (17). These, in turn, might be related to the degree of production, release, and reception of neurotransmitters at specific brain sites. Unlike Huntington Disorder, an illness with psychiatric components whose expression is consequent to the presence of a single defective gene, the prevailing view of the psychiatric research community holds that psychiatric disease expression is likely polygenic in origin and vulnerability, and that the development of the disorders probably stems from a combination of environmental influences and underlying genomic structure. It appears that continued investigation is likely to result in progressively greater elucidation of genetic vulnerabilities to, and bases for, disease expression. Should this happen, as much psychiatric illness first emerges in child populations, targeted interventions, perhaps primarily pharmacologic, will hopefully prove to be useful to CAPs and their patients.

Conjectured screenings of children for genetically based disorders infer ethical risks, however. Medical records containing specific genetic data, both about the children and their parents, could precipitate stigma when the information is made available to health insurers or local communities. Approaches to assent and consent would likely require revision in light of this potential and, as well, in response to the possible development of entirely new treatment methods (18).

PSYCHIATRIC PRODROMES

Presaging the identification of specific genetic markers, the identification of subclinical aberrant behavioral or cognitive phenomena, often coupled with documentation of disturbed family genealogies, led to the suggestion of treatment for psychiatric prodromal symptomatology before its postulated full-blown expression in frank disorders. In other words, full disease expression might be headed off, thus sparing the child, and later the adult, the burden of chronic disease. Focusing largely

on schizophrenia, research institutions have studied the effects of interventions, with neuroleptic medications and at times family interventions, on individuals exhibiting schizotypal symptoms with positive family histories for the disease. While the intentions are noble, that is, to spare children distress by providing pre-emptive treatment, thoughtful critiques have accompanied the efforts (19,20). Aside from obvious ethical concerns about the potentially debilitating effects associated with the introduction of neuroleptic medications, it is clear that determination of disease prevention is difficult to ascertain as in no way could one conclude which specific individual was in fact destined to develop severe illness. Thus, for example, the individual who has been so treated and does not develop psychosis years later may never have been destined to do so in the first place.

Despite such cautions, these preventive approaches continue in designated settings and may gain strength with advances in genetic understandings of psychiatric disease mechanisms. As many psychiatric disorders first emerge in childhood, proposals to treat any number of them pre-emptively are likely to be made. The ethical risk-benefit analysis called for at those times would need to be based on the nature of the then-current scientific knowledge base, potential benefits of new and positive interventions, and possible negative impacts. Given children's cognitive immaturities, CAPs would need to be very aware of the latent deleterious impacts on future brain and motor development, while desperate families might want to focus exclusively on the potential benefits.

SOCIAL MEDIA (BOUNDARIES AND PROFESSIONALISM)

For the older practitioner, social media is a novel technology to be mastered or approached gingerly. For the younger practitioner, and most definitely for the child through TAY population, social media have "always" been there and fluency with their use is a given. Vast majorities of populations worldwide are adept at communicating electronically via e-mail, Twitter, Instagram, Facebook, and the like. This widespread employment of digital communications requires CAPs' awareness of potential ethical pitfalls in their electronic dealings with patients and their families, and of ethical considerations as a component of practitioners' adherence to professional behavior.

Roberts and Dyer view professionalism as a concept expressed via ethical behavior and thought, that is, as applied ethics (21). Ideally, the physician's professional behavior encourages the patient's trust in the practitioner and solidification of the physician–patient relationship. Professionally set boundaries serve as an envelope that promotes and enforces pro-therapeutic behaviors; transgressions or frank violations of these boundaries pose the major threats to this supremely important relationship. These boundaries, some discussed earlier and all of which are subject to transgression, include patient's confidentiality rights,

practitioner conflicts of interest and eschewing of transparency, child exploitation, provision of informed assent and respect for dissent, and inappropriate romantic or physical contact with the patient and the patient's relatives (22,23). The ethical considerations surrounding electronic communications and boundary violations, however, can seem new and become quite complicated, particularly for the unwary CAP (24).

It is crucial for CAPs to know that internet use has been adopted by huge numbers of people, their access to countless quanta of digital communications is easily achieved, and these communications, therefore, however they might be intended, are not private and are recorded in perpetuity. Further, CAPs' blog posts concerning patients may violate their legitimate expectations of confidentiality; practitioners' personal information is readily accessible to patients; information about patients and their families exists in the public domain, is open to exploration by the CAP, and might possibly be obtained without the patient's knowledge and consent; and electronic communications between CAPs and their patients or family members can easily become public, by unintended breach or error, and, dependent on the nature of their interpretation, could potentially lead to professional liability. Liability concerns could include errors committed by practitioners secondary to receipt or sending of inadequate evaluation information; patient responses based on recommendations received via electronic versus face-to-face meetings; practice of medicine across states while lacking proper medical licensure; and inadequate documentation of electronic communications in the medical record. The not unusual, delicate dance of ethically balancing a patient's privacy rights with those of the parent's right to know can become all the more complicated when both parties are permitted, encouraged, or expected to engage electronically, but separately, with the practitioner. Given all of these scenarios the CAP is strongly advised to be knowledgeable about electronic communications, use them judiciously but not as a substitute for face-to-face contact, and be aware of the need to maintain professional demeanor while simultaneously remaining alert to legal liability potentials.

NEUROETHICS

Research efforts have consistently indicated that central nervous system stimulant medications are the treatments of choice for children competently and accurately diagnosed with attention deficit hyperactivity disorder (ADHD). Appropriate use of the medications benefits these youngsters by increasing their abilities to attend and concentrate, and improving their time management and executive functioning. In this fashion deficited youngsters are enabled to compensate for their diagnosed impairments and can learn and participate with peers in more equal fashion. However, research efforts also indicate that not only youngsters with ADHD benefit from this medical intervention but that segments of nondisordered, or "healthy,"

individuals, respond similarly (25). Thus, "normal range" individuals who access such medications may have their skills "artificially" enhanced, possibly advantaging them over their peers who do not use, or have access to, these resources. The emerging field of neuroethics engages in considerations and analyses of these conundrums (26).

How might pharmacologic agents be used? Are they intended only for the disabled or also for healthy individuals, possibly to enhance not only cognitions but mood as well? Ordinarily, CAPs must be alert to the potential deleterious effects of pharmacologic interventions with their patients, both for the immediate-term, for example, overt negative side effects, and longer-term, for example, the yet-to-be-known impacts of chronically administered neuropharmacologic medications on developing brain. But the potential benefits of the administration of such medications for "normal range" children raise additional and different sets of issues.

From the *justice* perspective—would such medications be available to all, or not? Might such cognitive enhancers, by artificially facilitating achievement, negatively impact the expectation of sustained effort expenditure in the pursuit of goals, a positively valued personality trait commonly encouraged during character formation in childhood? In 2012, 13% of the U.S. adult population was prescribed antidepressant medication in order to improve mood (27). Might an eventual generalized introduction of mood enhancers produce a happier or better-functioning society, or simply a more compliant one (28)? How would one measure the quality of outcomes when comparing results between medication-enhanced and -naïve students or athletes? Some of these questions are commonly debated in the larger society, about which, respectively, CAPs must be aware and to which they belong. For the moment, perhaps society's predominantly negative response to athletic-ability enhancement, on the part of professional athletes, is the best indicator of popular sentiment regarding medication-induced mood and cognitive enhancement for the "well."

INTERNATIONAL ETHICS

The United States, wedged between two large oceans, has periodically functioned as a country reluctantly forced to engage with the larger world. In this era of rampant globalization, however, that stance often becomes untenable. As is true across a variety of global matters, an openness to worldwide ethical concerns is crucial to America. While the fundamental ethical principles, discussed earlier, are universally acknowledged, their applicability must take cognizance of culture, context, and locale. Thus, political, geographic, economic, and religious influences and mores must be strongly considered by those individuals who suggest approaches to the provision of mental health care for children (29,30).

International efforts to create ethical codes intended for physicians worldwide

include the World Medical Association's (WMA) International Code of Medical Ethics, established in 1949 and subsequently revised, and the World Psychiatric Association's declarations, originally produced in 1996 and enhanced repeatedly since, that created ethical guidelines for psychiatric practice. In addition to ethical matters of expected address, such as concerns surrounding confidentiality, professional boundaries, and responsibilities to patients, the WMA's declarations specifically embrace prohibitions against participation in torture, enjoin discriminatory behaviors against ethnicities and cultures, endorse patients' rights to information about their diagnoses and the bases for prescribed treatments, and exhort avoidance of politically induced conflicts of interest. Specific child-centered concerns have similarly been addressed by international bodies. Thus, the United Nations Convention on the Rights of the Child (1989) delineated children's rights to survival, protection, and maturation, inclusive of the right to live with their families. The United Nations Convention on the Rights of Persons with Disabilities (2008) specifically includes children as it discusses those individuals afflicted by psychiatric disturbance.

The International Association for Child and Adolescent Psychiatry and Allied Professions (IACAPAP) created ethical guidelines in 2006 for practitioners worldwide that, in addition to setting out basic principles and expectations of proper patient care behaviors, highlighted concerns about potential child exploitation, sexual engagements, publication ethics, and multidisciplinary collaboration. IACAPAP's Declaration of Berlin (2004) focused, in part, on research approaches with children, declaring the priority of the individual child's welfare over other research goals, prohibition of involuntary child participation, and the imperative of proper assent and consent procedures.

Democratic forces, pitted in the past against totalitarian and authoritarian governments and responding to their cruel treatments of civilians, were pivotal in the creation of these documents. Medical support of, and collaboration with, the murderous Nazi machine of mid-twentieth century wartime Europe, and the creation of bogus diagnoses (e.g., the Soviet Union's use of "sluggish schizophrenia" to imprison political dissidents in psychiatric hospitals and mistreat them against their will), subsequently galvanized medical and psychiatric communities to create ethical standards in the effort to forestall similar future medical embarrassments. Current newspapers' front pages, replete with articles describing governmental-, tribal-, and religion-inspired chaos and mayhem that evinces no regard by its perpetrators for the rights of innocent civilians, as well as a democratic government's sponsorship, directly and indirectly, of state-supported torture (i.e., the United States and its international prisoners at Guantanamo [Cuba] prison as well as its secret international prisoner renderings to foreign governments), might seem to make a mockery of these noble declarations and documents. On the other hand, these documents continue to shine a positive light on medicine's and psychiatry's most

honorable ethical aspirations, with the hope that they might prevail during or after the direst of circumstances.

Apart from political contexts, economic factors have played large roles in the creation of these documents. As global studies indicate that up to 20% of child populations suffer from mental health disturbance, it is noteworthy that, in many countries, these children are homeless, often refugees living with or without their families, orphans, and abuse victims (31). A majority of these children live in resource-poor countries. Recently, though, many more have inundated relatively resource-rich Europe, having arrived from the Middle East and Africa and achieved at least temporary residence. Their needs are great. The ethical imperatives to provide for those needs and to avoid harm, endorsed by these above documents, continue to operate, independent of locale.

In most countries, the ability to prescribe best interventions for the individual child patient, as well as for children viewed as a group, is limited by the available resources. Thus, in certain locales custodial institutions may be the only prescriptive possibility for an autistic child, versus possible accessibility, in well-endowed settings, of therapeutic schooling, school-based aides, occupational and other therapeutic guidance, and additional state-funded programs. Similarly, psychotropic medications of differing chemical classes might be missing entirely from formularies in resource-poor countries. Differing cultures also affect ethical choices. Thus, cultures that place greater emphasis on the value of societal maintenance in contrast to the needs of the individual will probably unconsciously influence the ethical reasoning processes of the conflicted child care practitioner. As well, the CAP working in settings with limited available resources is likely to focus on mental health applications that can be applied to groups, while focusing training in mental health care on nonmedical child care workers in order that they be enabled to provide care for individual children (32–34). Finally, it is of interest that while differences exist between countries with regard to resources, measurements of the incidence of psychiatric illness, and treatment approaches, by contrast it appears that the values ascribed to fundamental ethical principles are similarly shared and respected across disparate borders (35).

ETHICS, FORENSICS, AND THE LAW

Ethical thought is intended to help guide individuals' behaviors in directions that benefit fellow human beings and their societies while respecting each individual's autonomy. Ethical exhortations of clearly preferred behaviors are usually presented in flexible fashion that allows for differing choices in their implementation. By contrast, the law's intent is to codify these ethical goals within relatively firm and defined limits. To wit, Potter Stewart, a former associate justice of the U.S. Supreme Court, breezily distinguished between the two disciplines: "Ethics is knowing the

difference between what you have a [legal] right to do and what is right to do."

Principle X (tenth), a recent addition to AACAP's Code of Ethics (7), deems it an ethical imperative, for the properly practicing CAP, to be fully cognizant of the laws governing medical and psychiatric practice of the jurisdictions in which the physician works. Thus, in addition to knowledge of generic legislations regarding medical responsibilities and negligence, documentations of care, and information release, CAPs are expected to be cognizant of the operative laws regarding custodial arrangements and responsibilities, child abuse and neglect, reportage requirements, responses to patients' expressions of harm directed against self or others, and assent and consent to medical care. While ethical inclinations and legal requirements often coincide, in some circumstances they may conflict. At those times, it is ethically incumbent on the CAP to recognize these conflicts and the various implications, for the patient and the physician, of the choices subsequently made by the psychiatrist.

In addition to responsibility for knowledge of relevant laws, the following comments address a smattering of other legal matters that may crop up in the course of CAP practice. Patients and their guardians must be alerted, by CAPs, to factors that distinguish between forensic and psychiatric evaluations (36). The former is intended to be impartial, objective, and not therapeutic. The evaluating CAP owes primary responsibility to the requesting party, commonly the juvenile justice or school systems, to render a sound medical opinion. That opinion may run counter to the child's preferences, though the evaluator is expected simultaneously to consider and acknowledge the child's needs. By contrast, a treating CAP has an ethical responsibility to make the needs of the child patient paramount. Furthermore, confidentiality rights do not apply in the forensic setting. The forensic evaluator must include all relevant data, inclusive of the patient's verbalizations, in the forensic report, and must utilize this data to substantiate the rendered opinions. By comparison, the treating psychiatrist is bound by the patient's confidentiality rights. A treating CAP, therefore, should avoid adopting a forensic role with the CAP's patient as combining the two roles potentially creates clear conflicts of interest, endangers the CAP's objectivity, diminishes the acceptability of the report, and could create havoc in the therapeutic relationship (37).

As a separate matter, when presenting release of information forms for guardian signature or responding to requests for information, CAPs have the ethical obligation to request or provide only that information necessary for the provision of care. Request or provision of more information than needed could be viewed as negligent practice. In related fashion, CAPs have ethical and professional responsibilities, to themselves and their patients, to be honest in their dealings, even in the face of health insurance companies whose primary motives appear to be solely financially driven. Therefore, CAPs must complete insurance forms, including diagnostic codes, honestly, even when doing so might negatively impact their patient's welfare.

Finally, complaints are periodically addressed to the AACAP's Ethics Committee

concerning alleged violations of professional ethics by CAPs. To date, the committee has largely functioned in an educational role for the parent organization, though more recently it is seeking an advisory role as well. The committee has not, however, due to a paucity of resources, ever engaged in investigational or quasi-judicial activities. In the event of the receipt of nonanonymous allegations of ethical violations against members, complainants are referred by AACAP's ethics committee to the ethics committees of the American Psychiatric Association's district branches and to state medical licensing boards. Following their investigations, subsequent ethical and legal decisions range from "no findings" to such sanctions as the loss of medical licensure to practice, with intermediary penalties inclusive of formal reprimands and temporary license suspensions. The loss of medical licensure by a CAP under these circumstances automatically leads to loss of membership in the AACAP.

CONCLUSION

Ethical thought provides the bedrock for guidelines and standards created for the practice of medicine and the profession of CAP. Professional conduct requires adherence to these standards and encourages awareness of these matters in the course of daily practice. Commonly, practitioners are not consciously aware of ethical dilemmas until they find themselves experiencing sticky situations. Those are ideal times to consult the AACAP Code of Ethics, members of the AACAP Ethics Committee, and respected colleagues. Often, optimal ethical results follow from the physician's opting to view dilemmas from a patient's perspective and following that lead (38).

CHAPTER 1.3 ■ A HISTORY OF CHILD PSYCHIATRY

DEBORAH BLYTHE DOROSHOW

INTRODUCTION

Most discussions of the history of modern child psychiatry describe a haphazard process by which many different intellectual and therapeutic movements directed toward the mental health of children coexisted and ultimately coalesced. Leo Kanner (1), considered by many to be the father of child psychiatry, lamented in 1971 that "child psychiatry is the result of the convergence of a number of interests which for about half a century have existed alongside each other, with only sporadically and tenuously maintained areas of mutual contact." In one lecture, Kanner described the "parade of segments" as they passed by, from the care of intellectually disabled children to the creation of intelligence testing, the formation of the field of developmental psychology, the rise of psychoanalysis, the child guidance movement, and finally his own arrival among pediatricians at the Harriet Lane Home of the Johns Hopkins School of Medicine. Neither was this parade an organized one. As Kanner (2) later described, "Collections of different shapes and sizes of building stones, for a long time not even conceived as such, were piled up at some distance from each other, then brought haphazardly into casual relationship, and eventually carried together to become parts of an integral edifice."

TROUBLED CHILDREN IN THE NINETEENTH CENTURY

Professional discussion of mental illness in children during the nineteenth century was negligible, if only because it was generally believed (and famously stated by American psychiatrist Benjamin Rush) that children's minds were too unformed to absorb the permanent disfiguration required by insanity (3). Primarily, such children were discussed as case reports of extraordinary children with bizarre behavior. For example, British psychiatrist Alexander Walk (4) described one 4-year-old boy reported in 1846 to "[have] been refused an outing and on becoming excited over this was punished; he then went into paroxysms of terror, was violent, and finally passed into a state of stupor described as 'idiocy'." Although large numbers of mentally ill adults resided in public and private asylums by the mid-nineteenth century in both Europe and the United States, few children resided in these institutions (5).

Although the practical aspects of care of mentally ill children are unclear, many physicians were writing about the concept of what they then referred to as "insanity" in young people. For example, prominent British psychiatrist Henry Maudsley (6)

devoted an entire chapter of his renowned 1867 textbook to the subject. Maudsley's work set a standard for such textbooks, in which childhood insanity would more frequently be considered separately from "feeblemindedness" and neurologic disorders like epilepsy. Still, childhood insanity was believed to be very rare. Maudsley (7) himself commented: "How unnatural! is an exclamation of pained surprise which some of the more striking instances of insanity in young children are apt to provoke … [but] Anomalies, when rightly studied, yield rare instruction."

INTELLECTUAL DISABILITY AND THE RISE OF INTELLIGENCE TESTING

Professional work on intellectually disabled children, described as "mentally defective," "feebleminded," or "idiots," was much more common, as well as more organized. In France, Jean-Étienne Esquirol and his colleague Edouard Seguin worked intensely with this population. By the late twentieth century, many such children were institutionalized in the United States (8,9). This population would become critical to the development of intelligence tests in the United States. French researcher Alfred Binet and his student Theodore Simon developed the first modern intelligence test in 1905 when Binet was commissioned by the French government to create a means of separating out intellectually disabled children for special schooling when compulsory public education became law. The test was unusual in that it attempted to quantify intelligence and was based on data from real children, representing a departure from strict theorizing. In 1916, Lewis Terman modified Binet's original intelligence test and introduced the Stanford-Binet revised edition for use in the United States (10).

American psychologist Henry Goddard appropriated and popularized this test in the United States. Previously, physicians had used a number of competing classification systems to identify intellectually disabled children, ranging from their degree of impairment to physical symptoms, the supposed etiology of impairment, or a child's ability to function socially. As the psychologist at the Training School for Feeble-Minded Girls and Boys in Vineland, NJ, Goddard demonstrated that Vineland students' scores on Binet's tests correlated well with teachers' assessments of their performance. In the process, he redefined "feeblemindedness" as a lack of intelligence, as opposed to a vague hereditary condition. In Philadelphia and Boston, psychologist Lightner Witmer and physician Walter Fernald conducted similar research on intellectually disabled children, focusing on how intelligence testing could be used to measure degrees of intellectual disability.

Intelligence testing in early twentieth-century America was an inherently eugenicist project. This was only natural for a project that intended to sort normal from abnormal; eugenics was at its heart an attempt to identify the best specimens of the human race and do away with the worst. For example, Henry Goddard and Lewis

Terman were strong supporters of eugenics; Goddard even promoted the passage of eugenic sterilization laws in his home state of New Jersey. In his most famous case study, *The Kallikak Family,* Goddard did extensive pedigree work to argue that a girl at his training school whom he described as feebleminded had become such due to a long family history of intellectual disability, poverty, and crime. Thus, he argued, intellectual disability was fundamentally heritable (11).

CHILD STUDY AND THE DESCRIPTION OF NORMAL DEVELOPMENT

As researchers like Goddard focused on identifying abnormal children, other researchers directed their attention to understanding the processes of normal child development. As childhood began to be recognized as a special stage of life in the late nineteenth century, these researchers described the period as encompassing multiple stages of development through which all children had to pass sequentially. These efforts took place under the umbrella of the child study movement, which quickly grew to involve not only pediatricians and psychologists, but also mothers who were anxious to implement the latest scientific knowledge into their childrearing practices. The professional figurehead of the movement was Clark University psychologist G. Stanley Hall, who identified the period of adolescence as a transitional one between childhood and adulthood in his most famous work, the 1904 study *Adolescence.* In the same study, he famously argued that the stages of child development recapitulated human evolution (12).

Hall's graduate student Arnold Gesell took an even more granular approach to child development, describing a series of emotional and physical milestones by which every physician and parent could assess a child's progress. Gesell put his theoretical work into practice in 1911 when he founded the Yale Clinic of Child Development, which later became what is known today as the Yale Child Study Center. His work was especially novel in that he employed new technologies, namely one-way mirrors and films, to observe and record children's behavior. Mothers were active participants in the Child Study Movement as well. Through the Child Study Association of America, middle class women studied G. Stanley Hall's writings together and kept detailed records of their childrearing which they sought to understand using the latest psychological principles. In the 1920s and 1930s, so-called child study groups enabled mothers to share their experiences with one another using the psychological framework of child development. These groups provided a safe space for mothers to discuss their anxieties and uncertainties about childrearing. In the 1940s, efforts to educate women in normal childhood development expanded through local PTAs, home economics courses, and classes for expectant women (13).

Child researchers like Gesell not only sought to describe child development; they

also became coveted sources of advice for new parents during the rise of what historian Rima Apple has called "scientific motherhood," or the idea that mothers were incapable of raising their children properly without consulting expert scientific advice on the matter. This concept dated to the late nineteenth century. In 1894, pediatrician Luther Emmett Holt advised a strict approach to childrearing in his *Care and Feeding of Children,* including early toilet training and strict discipline. Meanwhile, the United States Children's Bureau published regular pamphlets on infant care which stressed the importance of scheduling feedings, promoting a child's ability to self soothe, and addressing bad habits early. In the 1920s, the dominant figure in the child-advice field was behaviorist psychologist John Watson, who published a widely read book entitled *Psychological Care of Infant and Child* that encouraged parents to use conditioning to rid their children of bad habits, and warned mothers not to coddle their infants by kissing or hugging them excessively. In many ways, his work was a logical continuation of the advice given by Holt and later by the Children's Bureau. Watson's advice gained great popularity in the 1920s as a highly scientific, straightforward approach to child rearing. Discipline, Watson explained, should occur not by traditional means like spanking, but by reinforcing good behavior and ignoring or isolating a child in response to bad behavior.

By the 1930s and 1940s, childrearing advice had softened, using a more child-centered approach in which parents would encourage their child's natural development, taking cues from their children rather than imposing schedules and behaviors upon them. Pediatrician C. Anderson Aldrich and Mary Aldrich were some of the first to advocate so-called "permissive" child rearing in their 1938 *Babies are Human Beings,* followed by Yale professor Arnold Gesell and his colleague Frances Ilg in their popular 1943 work, *Infant and Child in the Culture of Today*. By the time psychoanalyst and pediatrician Benjamin Spock reassured parents that "you know more than you think you do" in the first edition of his 1946 bestseller *Common Sense Book of Baby and Child Care*, permissiveness was here to stay (14).

PEDIATRICS AND THE HEALTHY MIND

As the parental advice industry flourished, pediatrics was developing as a medical specialty focused not on a specific organ system but on an age group. Although physicians like Abraham Jacobi had focused their medical practices on children since the 1860s, pediatrics was first formalized when the American Medical Association inaugurated a Section on the Diseases of Children in 1880, acknowledging that children were fundamentally different, physically and emotionally, from adults. In 1930, the American Academy of Pediatrics was founded and by 1933 there existed a formal licensing board. In the realm of clinical practice, well baby clinics flourished after World War I, a natural outgrowth of milk stations which provided quality-controlled milk and health advice to mothers at the turn of the

century. While child study experts were providing detailed charts describing normal childhood development in the 1920s and 1930s, their counterparts (and sometimes even those same experts, like Gesell) provided charts detailing normal heights and weights (15).

In the midst of this focus on normal children arrived Leo Kanner, a psychiatrist trained under the formidable Adolf Meyer at Johns Hopkins. In 1930, the White House had convened a special Conference on Child Health and Protection, for which a subcommittee was assigned to study "Psychology and Psychiatry in Pediatrics." The subcommittee concluded not that psychiatrists should see children, but that there was a great need for general doctors to understand the basics of psychiatry (16). That same year, Meyer dreamed up the idea of setting up a psychiatric consultation service at the Harriet Lane Home, the epicenter of pediatric activity at Johns Hopkins. His goal was to examine "the rank and file of patients in the pediatric clinics for the formulation of psychiatric problems"—essentially, to learn about the psychology of children not through examining selected mentally ill children, but by observing every child who walked in the door of the pediatrics department (17). It was through this unusual one-man project that Kanner observed and treated children, both normal and abnormal, gleaning the information with which he would write the first textbook of child psychiatry in 1935.

Although Kanner certainly considered himself the founder of the field, this is a shortsighted view. His work at the Harriet Lane Home was certainly an important moment of interaction between pediatrics and psychiatry, but it was a much longer tradition of child saving, juvenile justice, and child guidance that gave rise to the profession of child psychiatry we know today.

CHILD SAVING AND THE MENTAL HYGIENE MOVEMENT

Beginning in the mid-nineteenth century, an enthusiastic generation of reformers, many of them women, became concerned with ensuring the physical and emotional well-being of neglected or mistreated children. They founded organizations opposing the cruelty of children, built lodging houses for working boys and girls, and sent poor children to live with families in rural areas in the so-called "Orphan Train" movement (18). Until then, many unwanted or dependent children had lingered in houses of refuge, where they were often subject to abuse and horrid physical conditions. In the mid-nineteenth century, reformers constructed orphanages to provide a more kindly (yet still relatively custodial) place for children to stay (19). Even reformatories, custodial institutions introduced in the 1820s for "delinquent" children, were increasingly concerned with engendering proper moral values (20,21).

By the late nineteenth century, reform efforts swelled into a full-fledged "child saving" movement, which focused on improving the welfare of dependent and

neglected children by ending child labor, promoting compulsory progressive education, providing school lunches, and creating a multitude of agencies designed to help dependent children (22). In 1912, the federal government announced its involvement in child saving with the creation of the United States Children's Bureau. The Bureau, administered by a group of highly educated, single women, quickly became an authoritative voice on child welfare. Among a wide range of activities, the Bureau's staff worked to end child labor, conducted studies on the social factors contributing to infant mortality, and advised new parents on prenatal and infant care (23). The work of the Children's Bureau culminated in the 1921 Sheppard-Towner Maternity and Infancy Act, which provided federally funded preventive health care to mothers and children for the first time.

Meanwhile, the mental hygiene movement was bringing psychiatry out of the asylum and into the larger community, shifting its attention from treatment to prevention. New leaders, like Johns Hopkins psychiatrist Adolf Meyer, suggested that mental illness might be influenced by both heredity and environment (24). If a person's early environment could be modified, perhaps mental illness might be prevented entirely. Because of its preventive focus, mental hygiene was especially directed toward children, who were deemed the most vulnerable and most promising sector of American society (25). Juvenile delinquency was first on the agenda. At the turn of the twentieth century, delinquency was still considered a fundamentally legal problem, often stemming from inherited degeneracy. Many children deemed delinquent or at risk for delinquency, continued to be sent to reformatories, which often remained prison-like even with the introduction of cottages and housemothers.

A new approach emerged in 1899 with the creation of the first juvenile court in Chicago. Juvenile courts, which emerged throughout the United States in the first two decades of the century, were not just courts for minors but rehabilitative agencies. Children, usually from the working class, were brought in for status offenses like truanting or running away from home, petty and serious crimes, and age-inappropriate behaviors like drinking or gambling. In the court, which had no jury or lawyers, the judge would offer individualized guidance, and a probation officer would serve as the child's mentor. Reality often proved sobering, as some juvenile courts became mere detention centers or distribution centers for unwanted children. Yet the juvenile justice system signified an important shift in the way delinquency was understood. No longer the straightforward act of breaking the law, delinquency was starting to become an expression of both psychological and socioeconomic stressors, a reconceptualization that would only continue over the next several decades. Chicago psychiatrist William Healy was also instrumental in changing this perception; in his 1915 book, *The Individual Delinquent,* Healy stressed the importance of understanding each individual child as a product of his or her environment and used psychological language to understand the motives of a "delinquent" child (26).

Mental health experts at the National Committee for Mental Hygiene (NCMH),

which was the flagship organization of the mental hygiene movement, hoped to use their institutional clout to create programs that would not only treat, but also prevent delinquency. In 1922, NCMH director Thomas Salmon teamed up with the Commonwealth Fund, a philanthropic organization that was hoping to start a child welfare initiative, to find a Program for the Prevention of Delinquency. In an effort to approach juvenile delinquency from as many angles as possible, the program placed social workers in schools to identify children in need of help, created a Bureau of Children's Guidance in New York City to train psychiatric social workers, offered psychiatric consultation to juvenile courts, and used public outreach to raise awareness of the importance of good mental hygiene. As part of the program, the Fund and the NCMH set up demonstration clinics to treat delinquent children based on a new model that had emerged a decade earlier at William Healy's Chicago Juvenile Psychopathic Institute. When the Commonwealth Fund and NCMH began to set up similar clinics in seven new cities starting in 1922, only one other clinic, the Judge Baker in Boston, existed. By 1942, the Fund had helped set up 60 child guidance clinics across the country (27).

CHILD GUIDANCE AND RESIDENTIAL TREATMENT

Initially child guidance clinics were intended to treat delinquent, typically working class children, who were referred there from juvenile courts. Almost immediately, however, clinic professionals began to identify a new population of patients: "predelinquent" children. These typically middle class "troublesome" or "problem" children had minor emotional and behavioral problems ranging from enuresis to temper tantrums and truancy. Most importantly, they had a better prognosis than delinquent children, many of whom came from poverty and tended to be repeat offenders. In order to treat them, teams of psychiatrists, psychologists, and social workers worked with child and parents to understand the origin of the problematic emotions or behavior, often tracing it to the child's relationships with his parents, especially his mother. Often, a child's problems were gendered in tone—a teenage girl might be brought to a clinic because of her sexual activity, for example. At the clinic, each team member played a different role. The psychiatrist interviewed the child, while the psychologist conducted a battery of tests and the social worker spoke to the parent(s). These roles were rigid and by no means equal; the psychiatrist was typically male and led the team, while the social worker, usually a woman, played a subservient role. Despite their appeal to a middle-class population struggling with the birth of a new peer culture amongst children and adolescents, child guidance clinics had many limitations. Most significantly, children with serious or intractable conditions like epilepsy, intellectual disability, or schizophrenia were not welcome (28).

The efforts of mental hygiene experts, including child guidance professionals, to

identify and treat a vast, previously unidentified population of "troublesome" children had many consequences, both expected and unexpected. With increased preventive work and efforts to identify and work with "problem children," experts identified a large number of children requiring help. One psychiatrist observed in 1935 that "With the excellent work accomplished by [child guidance], or rather in spite of it, there is a steadily increasing number of children under 15 years of age requiring … treatment" (29). This phenomenon, he explained, might also be due to a gross increase in the number of children with problems. However, it seems likely that the active work of the NCMH and other mental hygiene organizations to promote mental health and identify at-risk children in schools contributed to the perception of this increase.

Throughout the 1930s, 1940s, and 1950s, mental health professionals struggled to find a place for children who did not fit the mold of any existing community resources. These children had been rejected by their families, their schools, and their communities for being unruly, unmanageable, and incomprehensible. Before the mid-twentieth century, many of them would have been sent to custodial institutions after failed attempts to help them at home, at school, and in the community. In their midst arose residential treatment centers (RTCs), a heterogeneous group of institutions often transformed from punitive training school, orphanages, and other custodial institutions to meet the need of a new population of seriously troubled children now defined as "emotionally disturbed." Some RTCs were affiliated with universities, some with private philanthropic institutions, and others with state mental health systems. Despite their differences, all RTCs shared the mission of caring for this population of deeply troubled, rejected children. They also shared a commitment to the concept of the therapeutic milieu, an idea first introduced in postwar England among troubled war veterans. Professionals who adopted the therapeutic milieu approach fundamentally believed that every aspect of a child's stay, from meals to games, bedtime routines, and interactions with staff members, had the potential to be therapeutic (30).

RTCs also generally shared a commitment to a psychodynamic, or modified psychoanalytic, context (31). Psychoanalysis, based in large part upon Freudian concepts, had become central to American psychiatry in the first two decades of the twentieth century (32,33). In the late 1920s, Anna Freud in Vienna and Melanie Klein in London, among others, had begun to write about and practice psychoanalysis on young children (34). During World War II in Britain, the evacuation of children to the countryside and the involvement of many mothers and fathers in military work meant that parents and children were often separated. This phenomenon provided fertile ground for psychoanalysts studying the effects of separation and war on anxiety, personality development, and behaviors like bedwetting and delinquency (35). In the United States, the application of psychoanalytic concepts to children would influence not only child guidance, but residential treatment as well. Whereas professionals in

both arenas employed analysis as a means of understanding children, in many ways residential treatment embodied the practical application of psychoanalytic tools for daily interaction beyond the therapy hour.

INSTITUTIONALIZING A NEW PROFESSION

In the 1920s, psychiatrists who wanted to work with children could have participated in training programs associated with child guidance clinics, funded by the mental hygiene-oriented Commonwealth Fund and the Rockefeller Foundation. By 1940, the two organizations were funding training programs for 138 young psychiatrists. In addition to their work in child guidance clinics, many trainees also spent time training in pediatrics, neurology, and in psychoanalysis, which had become a standard part of any psychiatrist's training. Psychiatrists played an important role during World War II, helping to eliminate draftees whom they felt were "unfit" for service. As a result, the profession grew in size and prominence. After the war, the 1946 National Mental Health Act provided new federal training grants for psychiatrists, contributing to significant growth of the profession. Child psychiatrists were among those affected, and child guidance clinics continued to grow in number and size (36).

At the same time, child psychiatrists were building institutions to more formally organize their profession. This began in 1924 with the founding of the American Orthopsychiatric Association, an interdisciplinary group of child psychiatrists, psychologists, and social workers. During annual meetings of the group, clinic directors began to meet informally, gradually including more and more clinic staff. In 1945, this offshoot formally named itself the American Association of Psychiatric Clinics for Children and in 1947, established formal guidelines for child guidance clinics providing training in child psychiatry (37). In 1953, the American Academy of Child Psychiatry was founded, and in 1957 the American Board of Psychiatry and Neurology recognized child psychiatry as a subspecialty and established training standards for all new child psychiatrists (38). Although these events formally announced child psychiatry as its own subspecialty, in many ways they were merely capstones for a new style of practice that had been developing over the previous 30 years.

A MENTAL HEALTH "CRISIS"

Only 12 years after child psychiatry was recognized as a subspecialty, mental health policymakers announced that there was a crisis in child mental health. In the 1969 report of the Joint Commission on Mental Health of Children, *Crisis in Child Mental Health,* the authors estimated that there were 1.4 million American children in need

of mental health care, more than two thirds of whom were not receiving any treatment (39). In part, the perception of a crisis was based on the discovery of the Warren Commission that Lee Harvey Oswald, President John F. Kennedy’s assassin, had been an “emotionally disturbed” child who had failed to receive adequate treatment (40). How many other Oswalds might exist among America’s children, who might pose harm to themselves or others if they did not receive the treatment they desperately needed? The “crisis” in child mental health, experts believed, was primarily due to a large number of troubled children who were racial minorities from socioeconomically disadvantaged backgrounds. In part, this concept—and the sudden recognition that there were now millions of untreated mentally ill children in the United States—was driven by the theory that these children were raised in a “culture of poverty” characterized by pathologic families who deprived their children of the sensory and cultural stimuli required for normal development (41). It was no wonder, culture of poverty proponents argued, that these children became mentally ill.

Crisis or not, the identification of a large population of troubled children was problematic for a system largely unequipped to handle them. RTCs, child guidance centers, and child psychiatry units in hospitals were simply too few and too small to treat thousands of primarily poor, minority children. Furthermore, funding for existing infrastructure was declining rapidly as psychiatric institutions fell out of favor. One tragic result was the ascendance of the juvenile justice system as the primary caretaker for many mentally ill children, especially those from minority or low income backgrounds (42). Another was a greater reliance on shorter hospital stays and on using medications to treat childhood mental illness.

A BIOLOGIC APPROACH

Psychopharmaceuticals were latecomers to child psychiatry. The first modern psychopharmaceuticals were introduced into adult psychiatry in the 1950s. Yet few psychiatrists were employing medications for children until the 1980s, perhaps because treatment models remained focused on family dynamics and in many cases, retained an analytic grounding. By the 1990s, medications had become a routine part of child psychiatric practice (43). It was during this same time that both adult and child psychiatrists devoted new efforts to understanding the biologic basis of mental illness, looking for its basis in genetic inheritance and documenting its fundamental alteration of neurologic function (44). Starting in the 1980s, efforts to trace the heritability of childhood mental illness were particularly prominent in the field of autism research (45). In the 1990s, efforts to use advanced brain imaging to better understand psychiatric disorders in adults became a topic of interest in child psychiatry as researchers looked to imaging as one tool that might help them better understand both normal and abnormal development. These efforts, although novel, did not preclude study of the multiple, interrelated etiologies of childhood mental

illness. In fact, the biopsychosocial model, introduced in the 1950s to emphasize the biologic aspect of mental illness and reintroduced in the 1970s to emphasize the psychosocial aspect of medical illness, remains a dominant concept in child psychiatry (46).

Modern child psychiatry is a flourishing subspecialty comprised of physicians who work in interdisciplinary teams to serve children with complex psychosocial needs. Yet its biggest challenge remains providing necessary care to all the children who need it. As a June 2003 policy statement by the American Academy of Child and Adolescent Psychiatry (47) explained, "Despite the dramatic advances in scientific knowledge regarding childhood mental illnesses and their treatment over the past 20 years, only a small fraction of children suffering from mental illnesses receive treatment." The inability to provide mental health services to children who need them most is a function of multiple factors, including a shortage of child psychiatrists, lack of insurance parity, and reduced public funds available to children without the means to otherwise obtain treatment. Despite these challenges, promising changes like mental health parity provisions in the Affordable Care Act and programs which encourage medical students to consider careers in child psychiatry, as well as novel therapies for childhood mental illness, ensure that the history of child psychiatry will continue to be a rich one characterized by service to some of society's most vulnerable citizens.

CHAPTER 1.4 ■ EDUCATION AND TRAINING

DOROTHY E. STUBBE AND EUGENE V. BERESIN

Education is the most powerful weapon that you can use to change the world.
—Nelson Mandela

BACKGROUND AND CONTEXT

There is a national shortage of child and adolescent psychiatrists to care for the nation's youth with serious mental health needs and their families (1–5). Epidemiologic studies suggest that up to 9% to 13% of U.S. children and adolescents, ages 9 to 17, meet the definition of "serious emotional disturbance," with 5% to 9% suffering from "extreme functional impairment" (6–8). For adolescents, the estimates are even higher. The National Comorbidity Study of Adolescents reported 22% of adolescents aged 13 to 18 experienced severe impairments from emotional disorders (9). The approximately 8,500 practicing child and adolescent psychiatrists in the United States are considerably fewer than the estimated 20,000 needed to provide the psychiatric care of seriously psychiatrically ill children and youth within a multidisciplinary system of care (5). Child and adolescent psychiatry researchers are similarly insufficient to meet the need to advance our understanding of the etiology and treatment of these disorders (10–12).

Recruiting, training, and mentoring the next generation of child and adolescent psychiatrists is one of the major challenges, as well as one of the prime opportunities, of the field. Graduates face a plethora of career opportunities in clinical practice, academics, and research. Lifestyle and improving remuneration also draw medical graduates to the field (13). Yet there are many challenges facing training programs and obstacles to recruitment. Enhanced training requirements, a paucity of funding for graduate medical education (GME) of subspecialties, and depleted faculty time to provide the required mentorship and teaching are ongoing challenges. The vigor, rejuvenation, and satisfaction of training the next generation of superior physician clinicians and scientists are the enduring rewards (14).

CHILD AND ADOLESCENT PSYCHIATRY RESIDENCY TRAINING IN THE UNITED STATES

Historical Note

Child psychiatry in the United States began with the establishment of the child guidance clinics, the first of which was the Juvenile Psychopathic Institute in Chicago, established by Dr. William Healy in 1909. As child guidance clinics grew

in number and in size, it became clear that psychiatrists who worked with children required training that was more extensive and specific than that obtained in their general psychiatry residency. The Commonwealth Fund sponsored a major conference in 1944 which resulted in a standard set of skill areas that should be mastered by psychiatrists who treat children and their families. These skill areas included growth and development, psychodynamics, working with parents, administration, and community organizations (15).

In 1946, World War II was over and there was a renewed vigor to provide for the children of the new baby boom. The Mental Health Act of 1946 provided funding for the training of child psychiatrists. Additionally, the American Association of Psychiatric Clinics for Children (AAPCC) was formed. The AAPCC training committee provided an approval process for potential training sites, including an application and survey. About half of the child guidance clinics were approved as training sites in this manner.

The American Academy of Child Psychiatry (AACP), founded in 1953, was initially a by-invitation-only organization. The AACP was committed to ensuring training accreditation within the medical specialty, not only through child guidance clinics. After a debate of whether child psychiatry was more appropriately a pediatric or psychiatric subspecialty, the choice was made for psychiatry. The American Board of Medical Specialties (ABMS) approved the subspecialty in 1959 (16), and a total of 11 child psychiatry fellowship programs were accredited. The field has grown. As of 2016, there were 126 accredited child and adolescent psychiatry fellowship programs in the United States, and 827 filled fellowship positions in child and adolescent psychiatry (17).

Inextricably linked to subspecialty certification are standardized training criteria formulated through the Accreditation Council for Graduate Medical Education (ACGME). The ACGME Residency Review Committee (RRC) in Psychiatry oversees periodic surveys and determines the accreditation status of each training program. This approach was much more medically oriented than the earlier AAPCC reviews. The ACGME demanded that child psychiatry training programs be linked to accredited general psychiatry residency programs and to medical centers approved by the Joint Commission on the Accreditation of Hospitals. These requirements forced the child guidance clinics interested in training to abscond from their exclusive community roots and to become attached to medical schools. It also stimulated the development of new child psychiatry training programs that were situated in medical centers, rather than freestanding in the community.

In 1969, AACP opened its doors to all child psychiatrists who graduated from, or who were in training in, ACGME-approved programs. With the expansion of the specialty to capture the treatment of adolescents into its purview in 1989, AACP changed its name to the American Academy of Child and Adolescent Psychiatry (AACAP). The American Association of Directors of Psychiatric Residency

Training (AADPRT) and the Association for Academic Psychiatry (AAP) are more recently formed organizations specifically devoted to education and training (15).

As with all of medicine, training and education is both an art and a science. A good program director (PD) serves as the conductor for the symphony—transmitting a serious and passionate commitment to the highest standards of comprehensive care for children, adolescents, and families; a dedication to residents and their personal and professional growth and excellence as physicians; and a vision of the field—where it is now and where it needs to go. In each institution, the instrumentation and symphonic music will vary, but the basic principles apply. Excellence in training requires coordinated and well-constructed training experiences that adhere to all training requirements, within multiple systems (medical school, hospital, clinics), synchronized with the goals and structure of the broader administration (Dean, hospital administration, Chair of Department of Psychiatry, Child and Adolescent Psychiatry Division Head or Chair, Program Directors of Residency Training, and Designated Institutional Official) and harmonized with the resources and needs of the Division and Department.

Recruitment, Portals of Entry, and Training Program Types (Traditional and Novel)

Recruitment and Workforce Issues

A survey by Beresin and Borus of accredited child and adolescent psychiatry fellowships identified a shortage of recruits for residency and faculty positions in child and adolescent psychiatry in the late 1980s (18). This shortage has continued (5). Lack of exposure to child and adolescent psychiatry during medical school education, increasing levels of educational debt burden, long years of residency training, and relatively smaller income potential in the field of psychiatry, as well as in child and adolescent psychiatry, are factors that may influence a medical student's career decision (19,20). Other obstacles to recruitment include inadequate support in academic institutions, decreasing GME funding, and decreasing clinical revenues in the managed care environment (21).

In spite of the shortages, child and adolescent psychiatry has made impressive progress in its scientific knowledge base through research, especially in neuroscience, developmental science, and genetics (22). Additionally, there is a growing recognition of the need for child and adolescent psychiatry by policymakers and the public at large. The Surgeon General's Conference on Children's Mental Health in 2000 (3), and the President's New Freedom Commission on Mental Health in 2003 (4), have both acknowledged the shortage as a national crisis. There is increasing media coverage on mental health problems of children and adolescents, as the public becomes more aware and concerned about these vital issues facing our

youth. The public has become increasingly interested in issues of mental health and effective interventions, as the aftermaths of such disasters as Hurricane Katrina in the Gulf Coast in August 2005 and the shootings at the Sandy Hook Elementary School in December of 2012 have left not only physical, but also mental health scars on the population.

Recruitment efforts in child and adolescent psychiatry focus on three salient areas: (1) ensuring that talented, interested physicians have positive exposure and engagement early in medical training to the field of child and adolescent psychiatry; (2) providing training opportunities that are appealing and ensure ongoing engagement of the psychiatry resident and child and adolescent psychiatry fellow in work with children and families; and (3) the positive aspects of lifestyle, remuneration, and the plethora of job opportunities for individuals seeking a career in the field.

Traditional and Innovative Child and Adolescent Psychiatry Training Models

There has been an ongoing debate about the most effective, efficient, and appealing methods to train competent child and adolescent psychiatrists. There were early proposals that child and adolescent psychiatry should split from general psychiatry, as did pediatrics from internal medicine. There have been numerous other proposals, as well. The primary impetus for new and more innovative training portals are twofold: (1) a philosophy of training that endorses innovative training tracks to more fully ensure quality education of competent graduates by optimizing training methods; and (2) enhancing recruitment into the field by providing a variety of attractive and novel training portals. Figure 1.4.1 summarizes the current training pathways for child and adolescent psychiatry training.

Existing Portals

Traditional Child and Adolescent Psychiatry Training. Training in child and adolescent psychiatry generally occurs after medical school; after a first post graduate (PG-1) year that includes at least 4 months of general medicine or pediatrics and 2 months of neurology; and following the completion of at least 2 years of general psychiatry training. However, child and adolescent psychiatry training may commence any time after the PG-1 year. Training in child and adolescent psychiatry is for 2 years, and the first year of training may count for the last (PG-4) year of general psychiatry training. Thus, traditional training in child and adolescent psychiatry may be completed in either 5 years (referred to as “fast-tracking” when CAP training begins in the PG-4 year) or 6 years (when CAP training begins in the PG-5 year following completion of the full 4 years of psychiatry residency). A majority of residents enter in the PG-4 year. These residents are eager to work with children and families more intensively, and they may experience pressures to finish

training: to address family, finances, and career development issues, and for some, to plan ahead toward further training, such as forensics, addictions, or research fellowships. Other residents prefer to complete the full 4 years of general psychiatry training prior to starting child and adolescent psychiatry residency to take advantage of the opportunity for elective experiences, chief residency, and/or to consolidate skills in their work with adults (14).
FIGURE 1.4.1. Training pathways in child and adolescent psychiatry.

Integrated Training

Triple Board. An innovative 5-year training sequence in pediatrics, general psychiatry, and child and adolescent psychiatry, better known as the "Triple Board," began as a pilot training experiment in 1985 and was approved nationwide as a combined residency in 1992 (23). The "Triple Board" concept was to create an alternative pathway of training to become a child and adolescent psychiatrist that would combine pediatric, general psychiatry, and child and adolescent psychiatry training and would allow a path shorter than would be required in the conventional (additive) training sequence of 7 or 8 years. One of the goals of the combined training program was to create a nucleus of academically based child and adolescent psychiatrists who were trained and socialized as pediatricians, thus serving to bridge a gap between the pediatric and the child and adolescent psychiatry communities. Additionally, it was hoped that this core of "Triple Boarders" could serve as a magnet in the academic environment to attract medical students to the specialty field of child and adolescent psychiatry. This track is sponsored by the American Board of Psychiatry and Neurology (ABPN), the ABPN Committee on Certification in Child and Adolescent Psychiatry, and the American Board of Pediatrics (16). Follow-up

suggests that this training track has trained competent and successful clinicians and scientists, most of whom practice predominantly child and adolescent psychiatry, although often in a setting with medically compromised children (24). The rotations and integration of the three specialties varies from program to program, but all programs provide 24 months of pediatrics and 18 months each of general and child and adolescent psychiatry. Upon completion of training, residents may sit for Board examinations in all three disciplines. There are presently 10 approved Triple Board training programs.

Post Pediatric Portal Program. A newly initiated training model utilizes the Triple Board model for training physicians who have completed a core 3-year ACGME-accredited pediatric residency. The Post Pediatric Portal Program (PPPP) is a 3-year combined training program in general psychiatry and child and adolescent psychiatry which is formally approved and overseen by the ABPN. Graduates are Board eligible in both general and child and adolescent psychiatry. The PPPP allows newly graduated pediatricians or pediatricians who have been in practice for a number of years and wish to retool in child and adolescent psychiatry to do so in 3 years, rather than the usual 4. Currently, there are four PPPP training programs (25).

Other Integrated Training Tracks. Integrated training specifies a residency that combines training in two or more disciplines in a contiguous, rather than consecutive, training model. This approach, initially developed and implemented in the 1970s at the University of Pittsburgh by Peter Henderson, M.D., combined child and general psychiatry training from the onset of training. Since that time, a few more institutions have adopted similar models of integrated training. Other programs have the flexibility to initiate a variety of child and adolescent psychiatry clinical experiences within the general psychiatry residency for individuals with a declared interest. Although programs vary in the specific manner in which they configure training requirements, all share in common the principle of exposing residents early and continuously to children and childhood pathology (15).

Training programs with an integrated track meet all existing program requirements for residency education in both general psychiatry and child and adolescent psychiatry. Programs with integration seek to allow knowledge, skills, and attitude building in a developmental context of patient care, and to solidify the trainee's identity as a child psychiatrist early on. Most integrated training occurs within the context of a 5-year clinical training program.

Academic Integrated Training Tracks. In the United States, there is a dearth of academic child and adolescent psychiatrists to propagate the research base on the etiologies and effective treatments of childhood psychiatric disorders (3,10). Integrated training in general psychiatry, child and adolescent psychiatry, and research allows medical students to move directly into an integrated child–adult

psychiatric residency and research training program that is constructed to do justice to the basic developmental sciences and efficacious interventions while not neglecting the fundamentals of psychiatry. The major goal of this alternative training route is to provide a national model to increase the number and quality of child and adolescent psychiatrists in research careers.

In response to the Institute of Medicine's report on the shortage of psychiatrist researchers, the National Institute of Mental Health established the National Psychiatry Training Council (NPTC) (26). With the support of the NPTC, of which he was co-chair, Dr. James Leckman and others proposed 6-year integrated child and adolescent psychiatry academic track (10) that has become a reality at the Yale Child Study Center, the University of Colorado, and the University of Vermont and is being considered in other institutions. This program highlights three basic principles: (1) early identity formation as a child and adolescent psychiatric researcher; (2) the developmental continuity of training; and (3) individualization of training and "tooling" opportunities to prepare the trainee for a research career. The program has an internship year that includes pediatric medicine, followed by a cohesive curriculum that includes identification of a research team and mentor(s), and integration of full general psychiatry and child and adolescent psychiatry clinical training with research training over the subsequent 5 years (27).

The Transition from General Psychiatry Residency to Child and Adolescent Psychiatry

By the time a resident enters child and adolescent fellowship training he/she has had at least three initiations into new territory: medical school, internship, and general psychiatry residency. The entry into child and adolescent residency training is yet another "beginning," with the attendant narcissistic challenge of starting over and having to master new skills, having just achieved competence and confidence with adults. The loss of working with adults threatens losing skills acquired over 3 to 4 years.

Child and adolescent fellows working clinically with children use nonverbal skills, deal with primitive defenses, and manage behavior in individuals who are far less able to use advanced cognitive skills and concepts than the adults with whom they previously were quite comfortable. They also have to manage new and complex countertransference problems, such as the wish to "adopt" their patients, undo the actions of "incompetent" parents, and the susceptibility to overidentify with their child patients. They are mandated reporters, and must "turn in" parents to authorities. And they now must serve as authorities for schools, courts, and social service agencies in making decisions that have a profound effect on the child and family, including decisions about custody, placement, and incarceration—all at a time when they have relatively limited knowledge and skill in the field. They must shoulder the

responsibility of working with dying children and grieving parents. At a less intense level, they have to answer complex developmental and behavioral questions from parents, pediatricians, and allied professionals when they are themselves novices. The new fellows have to face all this in the context of increased time demands for calls, emails, documentation, and meetings. They need to help deeply troubled children and families at a time when there are limited resources for outpatient and inpatient care, and far too few clinicians in all child-related healthcare disciplines to take on referrals for the comprehensive care of the children and families they serve. Child and adolescent psychiatry is more demanding than general psychiatry, in that fellows need to embrace a developmental model that requires greater integration of the many factors that impact child development, such as genetics, family, culture, educational systems, and social forces. Additionally, child psychiatry training occurs at a time when many fellows are attempting to, or have established, new love relationships and families, and struggle to find precious time to spend with them.

Training programs need to appreciate the difficulty of the transition, and promote means for fellows to cope with these stresses. The effective collaboration between the fellowship program coordinator and the PD is crucial to this task. At the admissions level, screening for the most mature, adaptive, and resilient candidates is helpful. Trying to assemble a fellowship class that is cohesive and supportive is also useful. The program should provide time for residents to meet with faculty and discuss the issues and problems involved in the transition. Alerting the faculty to these transition issues is vital, so they may be addressed in individual supervision. Finding many opportunities to have fellows observe faculty treating children and families and serving as consultants provides the means for them to learn skills and have working role models for identification. It may be valuable for some fellows to continue treating adult patients, either in the program or through moonlighting, to help preserve previously acquired skills.

Milestones: Competency-Based Assessment in Child and Adolescent Psychiatry Training

The Core Competencies

The training of competent physicians is the goal of all residency training. In 1999, the ACGME (27) identified six core domains in which each resident is required to obtain competence (Patient Care; Medical Knowledge; Systems-Based Practice; Practice-Based Learning and Improvement; Professionalism; and Interpersonal and Communication Skills). Training programs must define the specific knowledge, skills, and attitudes required for competence in each of the six Core Competencies, and provide educational experiences as needed in order for residents to demonstrate competence (28–30).

The Next Accreditation System: Milestones

The Next Accreditation System (NAS) is a process initiated in 2009 by which the ACGME restructured its accreditation system to be based on educational outcomes (Milestones) of the six Core Competencies for all medical specialties. "The aims of the NAS are threefold: to enhance the ability of the peer-review system to prepare physicians for practice in the 21st century, to accelerate the ACGME's movement toward accreditation on the basis of educational outcomes, and to reduce the burden associated with the current structure and process-based approach" (31) (p. 1051). A key element of the NAS is the measurement and reporting of outcomes through the educational milestones: developmentally based, specialty-specific achievements that residents are expected to demonstrate at established intervals as they progress through training. In each specialty, the Milestones for each of the Core Competencies have been formulated through a collaboration of the ABMS certifying boards (the ABPN for psychiatry and its subspecialties), the RRC, medical specialty organizations, PD associations (for psychiatry, the American Association of Directors of Psychiatry Residency Training [AADPRT]), and trainees.

The NAS initiated a progressive rollout of Milestones and NAS indicators of program quality to GME programs in 2013. In July of 2014, general psychiatry programs began to implement psychiatry-specific Milestone monitoring, and in July of 2015, child and adolescent psychiatry training programs began to implement the Milestone performance data for each program's fellows to determine whether fellows overall are progressing. The ACGME Milestones provide five levels of competence, with specific behavioral skill anchors tied to each level. Tracking from level 1 to level 5 is synonymous with moving from novice to expert in the specialty. Level 4 is designed as the graduation target, although graduation has not been specifically linked to Milestone metrics. Level 5 serves as an "aspirational" goal for which it is expected that only a few exceptional fellows will reach prior to graduation (32,33). Upon completion of fellowship training, the PD must verify that the fellow has demonstrated sufficient competence to enter practice without direct supervision (34). Milestone metrics for each trainee are assessed by the program's Clinical Competency Committee (CCC) and entered semi-annually into the ACGME Accreditation Data System (ADS)—they are not currently being utilized for program accreditation purposes. Table 1.4.1 summarizes Competencies and associated Milestones.

The Next Accreditation System: Clinical Learning Environment Review

Another component of NAS is the Clinical Learning Environment Review (CLER). This is a periodic site visit of ACGME-accredited institutions by national field representatives. The CLER review provides feedback to the core training institution on the residency learning environment that addresses the following 6 areas: patient

safety, healthcare quality, care transitions, supervision, duty hours and fatigue management and mitigation, and professionalism (35). The feedback provided by the CLER program is designed to encourage clinical sites to improve engagement of resident and fellow physicians in learning to provide safe, high-quality patient care. The CLER program is separate from the accreditation process.

The Next Accreditation System: Program and Institutional Accreditation

Training in all of the medical specialties is well regulated for quality, to ensure that the training program is providing the full scope of experiences, didactics, and supervision in a suitable environment. The ACGME is responsible for setting training requirements for all specialties and subspecialties approved by the ABMS.

The General or Institutional Requirements are the same regardless of the specialty being reviewed. They are concerned less with the particular training area than with the overall support and surveillance provided by the medical center in which the training program is embedded. These issues include requirements for the selection of trainees and assurance that there are procedures for evaluation, feedback, grievance reporting, duty hours, and due process. There also must be adequate compensation, an emphasis on education rather than on service, and acculturation help for those trainees who need it (34).

TABLE 1.4.1

CORE COMPETENCIES AND MILESTONES IN CHILD AND ADOLESCENT PSYCHIATRY (CAP) FELLOWSHIP TRAINING

Competency	Definition	CAP Milestones
Patient Care	Compassionate, appropriate, and effective treatment of patients, which serves to promote health and recovery	PC1: Psychiatric Evaluation PC2: Formulation and Differential Diagnosis PC3: Treatment Planning and Management PC4: Psychotherapy PC5: Somatic Therapies
Medical Knowledge	Established and evolving biomedical, clinical, and cognate sciences, as well as the application of this knowledge to patient care	MK1: Development MK2: Psychopathology and Wellness MK3: Clinical Neuroscience and Genetics MK4: Psychotherapy MK5: Somatic

		Therapies MK6: Practice of Psychiatry
Systems-Based Practice	Actions that demonstrate an awareness of and responsiveness to the larger context and system of health care, as well as the ability to call effectively on other resources in the system to provide optimal health care for patients	SBP1: Patient Safety and the Health Care Team SBP2: Resource Management SBP3: Community-based Care SBP4: Consultation to and Integration with Nonpsychiatric Providers
Practice-Based Learning and Improvement	Investigation and evaluation of care for patients, the appraisal and assimilation of scientific evidence, and accessing of the evidence base for treatments to improve patient care	PBLI1: Development and Execution of Lifelong Learning PBLI2: Teaching
Professionalism	Commitment to carrying out professional responsibilities, adherence to ethical principles, and sensitivity to patients of diverse backgrounds	PROF1: Compassion, Respect, Adherence to Ethical Principles PROF2: Accountability to Self, Patients, Colleagues, Profession
Interpersonal and Communication Skills	Effective exchange of information and collaboration with patients, their families, and other allied health professionals	ICS1: Relationship Development and Conflict Management ICS2: Information Sharing and Record Keeping

The Special Requirements are the essential training components that are specific to a particular specialty or subspecialty. They are revised every 5 to 10 years, although discrete changes or “minor revisions” may be made between revisions. The revisions of the Special Requirements and the evaluation of the ACGME surveys are the responsibility of the RRC for each specialty. RRC members for psychiatry are nominated by three organizations: the American Medical Association (AMA), the ABPN, and the American Psychiatric Association (APA).

In the NAS, program accreditation has changed from “an episodic ‘biopsy’ model” (in which compliance is assessed every 5 years for programs in good standing) to annual data collection (31). The Psychiatry RRC performs an annual evaluation of trends in key performance measurements for each accredited training

program. In addition to the Milestones, other data elements for annual surveillance include the ACGME resident and faculty surveys and annual program information that is entered by the PD into the ACGME ADS. Programs conduct a self-study before the accreditation site visit, which is scheduled for every 10 years unless the annual metrics suggest concerns that require assessment by a more immediate on-site review. Programs are informed annually about accreditation status, any citations or areas for improvement (AFI) for noncompliance with training requirements. Accreditation with warning or probationary status may be conferred to programs with serious lapses in the required training components, or accreditation may be withdrawn for egregious violations.

Evaluation: Formative and Summative Assessments

Professional competence includes multiple skill dimensions that must be integrated in the care of patients. Epstein and Hundert (36) have defined this as "the habitual and judicious use of communication, knowledge, technical skills, clinical reasoning, emotions, values, and reflection in daily practice for the benefit of the individual and the community being served" (p. 226). They conceptualize competence as more than simply a demonstration of specific knowledge, skills and attitudes, but rather as the integration of ways of thinking, feeling and behaving that are synthetic, ongoing, context dependent, mindful, and in continuous development.

It is useful to conceptualize competency evaluation as formative or summative. Formative assessment, performed as a trainee learning tool, is optimally done early and often so that areas of strength or deficiency may be identified. This allows an ongoing means for constructive change, and serves as a tool to evaluate effectiveness of targeted learning interventions. Summative assessment evaluates the attainment of skills, usually at the completion of an educational experience such as a rotation, didactic seminar, or at the end of a training year. Summative assessments include annual examinations, such as the Child Psychiatric In-Training Examination (Child PRITE), a multiple-choice exam modeled after the ABPN Board Examination and with nationally normed scores. Another example of a summative examination is the annual clinical skills assessment, typically an assessed oral examination of competence of each trainee in diagnostic interviewing, formulation, and treatment planning. The specialty-specific Milestones are used as one of the tools to ensure fellows are able to practice core professional activities without supervision upon completion of the program (34).

The cornerstone of formative assessment is feedback. Feedback is defined as an information exchange between trainee and faculty describing performance in a particular activity. It is intended to assist in the acquisition of knowledge, skills, and attitudes. If executed properly, feedback should be done once specific goals and objective have been defined. It should be timely, ongoing, face-to-face, based on

first-hand data, objective, nonjudgmental, and allow a discussion of the process (37). Far too often in our medical schools and residency training programs, feedback is neglected, and residents receive either subjective superlative reviews (e.g., “great job!”) or hear about their daily performance only if something goes wrong.

Clinical Skills Verification (CSV) assessments may be conceptualized as both formative and summative. These exams are patient interviews that assess a fellow’s competence on the following skills: (1) physician–patient relationship; (2) conduct of the psychiatric interview; and (3) case presentation. Fellows must pass three CSVs at the competence level of a practicing physician with patients of age least two different age groups (preschool, school-age, or adolescent), and with at least two different Board Certified child and adolescent psychiatrist examiners as one component of eligibility to sit for the child and adolescent psychiatry Board Certifying Examination. Because these interviews may be embedded in the course of normal clinical care activities, may be completed multiple times, and have nationally approved rating forms with skill anchors, they may serve as an excellent method of providing feedback on important clinical interviewing skills, as well as being used as a summative assessment of eligibility to sit for the ABPN certifying exam.

One of the important consequences of a highly successful evaluation methodology is that it may provide an alternative model to the one used currently in residency training (38). Many of the ACGME requirements for residency training are timed: They require a certain period of time on a service or rotation for successful completion. This allows for a relatively stable and predictable process for training programs, but decreases flexibility for an individual resident. In a purely milestone competency-based training model, if a resident can demonstrate competency at a relatively early stage of training in a given area, more time could be devoted to other, more advanced or elective experiences. This could open up the training process to facilitate specialty training in a wide range of clinical, academic, or research endeavors.

Remediation

The enormous personal investment, as well as institutional and national investment in each physician, provides a crucial impetus to ensure that each resident competently complete training and enters the workforce to care for the large number of underserved children and families in need.

A failure to meet the core competency criteria in knowledge or skills in any of the six competencies can be described as a “deficiency” that must be made up, for example, through access to a missed learning opportunity or repetition of previously offered material (39,40). In contrast, the “remediation” of attitudes is a more difficult definition, which suggests that a change is required in a resident’s outlook (41). Health impairments, due to physical, psychiatric, or substance abuse problems, are special challenges to remediation, and have federal and state guidelines that must be

followed regarding the impaired physician and the safety of the public.

Remediation of competence is embedded within the overall philosophy of lifelong learning and improvement. At the start of any educational or training endeavor, the novice does not yet possess the knowledge, skills, and attitudes required for competence. Remediation is the act of identifying areas that are not yet performed competently and addressing them. Learners who are not making the progress expected of a resident at their level of training require remediation to ensure that the skill level is consistent with the expertise needed to perform the tasks with competence.

Competency-based training, assessment, and remediation utilize a skills-attainment model rather than an apprentice model of training. Except for the very rare circumstance in which a trainee has such an egregious violation of ethics and practice that termination is required, fellows should receive constructive feedback on strengths and relative weaknesses in their skill set, and be engaged and motivated for self-improvement on an ongoing basis. From this theoretical stance, training and supervision may be conceptualized as ongoing remediation—or remediation may be conceptualized as ongoing improvement of medical practice. Remediation is not discipline. It is only when a resident does not meet required expectations for improvement of practice that the process may move forward into a more disciplinary procedure.

If a trainee displays deficiencies in competence that are severe, pose a danger to the public, or have not been modified by a concerted and comprehensive remediation plan, the mediation process may need to enter into a disciplinary phase. Each institution has a Due Process procedure in place for trainees, and the PD should be familiar with the process and ensure that all fellows are informed of them, as well.

PDs of residency training are charged with the task of ensuring competent graduating physicians. The courts have strongly supported the academic judgment of professional faculty unless evidence of discrimination or other wrongdoing by the faculty exists. The courts view residents as clinician/faculty rather than students as far as disciplinary actions are concerned. As a matter of public policy, the courts support disciplinary actions, including dismissal of a resident physician, in the interest of public safety in the course of patient care (36). Component of competency-based assessment and remediation are shown in Table 1.4.2.

Faculty Development in the Age of Competencies

The incorporation of a competency-based curriculum in medical education requires new challenges to the faculty. First, they need to understand the conceptual basis for looking at outcomes in the educational process, assimilate the new language of the competency. Milestones into their lexicon, and embrace the process as not simply additional bureaucratic burdens, but rather a more effective approach to the educational mission. There is no doubt that building ongoing assessment into the

daily process of working with trainees will be more time-consuming.

The faculty needs to learn how to provide ongoing objective feedback and begin doing so. This will involve increased direct observation of trainee–patient interactions, as well as codifying ways of observing them. Training to improve interrater reliability among faculty members may improve consistency of assessments. Other standardized techniques, such as chart reviews and checklists for resident presentations, are needed. The faculty will increasingly be involved in multirater evaluations (formerly called 360-degree evaluations), and help implement these by engaging staff from other disciplines, and inviting patients and families to contribute. The faculty and residents will need to be more comfortable and familiar with the use of videotaped sessions, an excellent means of observing their interactions with patients. In-service programs are needed to help faculty learn new ways of teaching the core competencies. Examples include innovative collaborative rounds with pediatricians and schools in the care of patients with complex disorders as an effective method to teach systems-based practice. The Kalamazoo Consensus Statement on Communication Skills may be an effective means of learning to teach and assess Interpersonal and Communication Skills (42). Engaging faculty and residents in the creative endeavor of training keeps faculty up to date and fresh, as well as provides an optimal training environment for residents.

TABLE 1.4.2

COMPETENCY-BASED ASSESSMENT AND REMEDIATION: STEPS AND EXAMPLE

1. Clarify educational goals and instructional learning objectives for each rotation
2. Ensure educational outcomes are related to identified objectives that are observable and measurable
3. Identify trainee strengths and areas for improvement in the relevant Core Competencies (examples provided, but the table should be specific to the trainee)
4. Choose the Competency(ies) that requires remediation
5. Formulate a remediation plan that is specific and measurable, with a timeline
6. Consider assigning a Program Mentor that is not a direct supervisor/evaluator, to assist with remediation implementation
7. Agree upon the plan via joint signatures

Trainee: Dr. Smith	**Date: November 15**
Areas of Strength	***Areas for Improvement***
Interpersonal and Communication Skills	
Has demonstrated superior ability to communicate with patients around diagnosis, medication risks, and benefits	Has not demonstrated adequate problem-solving or effective communication in situations in which there are questions about coverage, vacations, or call
Is prepared and actively participates in Inpatient Rounds	Has avoided communicating with colleagues when there are areas of conflict
Calls outpatient treaters and communicates with referral sources	Has utilized ineffective or inappropriate means of communication—e.g., using e-mails and texts to publicly air grievances about a colleague or the program
Patient Care	

Clear commitment to patients and excellent care	Intermittent incomplete sign-outs to colleagues may adversely impact patient care
Professionalism	
High ethical principles for patient care	At times, avoidance of speaking directly with colleagues has negatively impacted professionalism
Patient care comes before self-interest	Has spoken negatively about colleagues in a public venue
Medical Knowledge	
Excellent knowledge base	
Usually very engaged in didactics	Inconsistent participation in didactics
Systems-Based Practice	
Generally collaborates well	Interpersonal conflicts have hindered team collaboration at times
Practice-Based Learning and Improvement	
Keeps up with the literature	Has avoided receiving feedback to improve performance

REMEDIATION PLAN: Competency–Interpersonal and Communication Skills

Dr. Smith (trainee) will collaborate with Program Mentor, Dr. Jones, on the following objectives to meet basic competency criteria prior to March 31. A reevaluation of competence will occur on or before March 31 to review progress and make a plan regarding promotion to second year.

1. **Dr. Smith will demonstrate consistent effective communication with colleagues, faculty, and collaborators around all aspects of residency duties.**
   a. Methods: Dr. Smith will
      i. discuss changes in schedules with appropriate colleagues, chief residents, and faculty, to ensure appropriate coverage;
      ii. ensure that all pertinent staff and colleagues are included in communication links;
      iii. talk to all collaborators;
      iv. meet for supervision and group meetings, as scheduled;
      v. problem-solve issues with other fellows, etc., utilizing meeting resources/supports provided;
      vi. communicate regarding needs and requests at the time that decisions are being made;
      vii. communication ideas and suggestions for positive change, and refrain from negative communication that may interfere with the educational experience of others.
2. **Dr. Smith will demonstrate an attitude of interest in feedback and self-improvement**
   a. **Methods: Dr. Smith will**
      i. meet twice monthly with Program Mentor, who will assist with skill acquisition via discussion, readings, feedback—with reporting back to Clinical Competence Committee on participation;
      ii. utilize direct feedback from Program Mentor and supervisors on communication effectiveness for gaining positive communication/interpersonal skills;
      iii. complete two Clinical Skills Exams with different attendings, and utilize feedback provided;
      iv. optional, but recommended—consultation with a therapist, psychiatrist in the community, or hospital Employee Assistance Program for support.

Program Director	Fellow

The competency movement and need for increased faculty training and participation comes at a time when the faculty is stretched more than ever—and at risk of providing suboptimal teaching. Lieff (43) has described a faculty development philosophy of "meaningful and aligned work." This conceptualization encourages faculty to reflect upon the aspects of their work that are most meaningful and align their career trajectories accordingly. Despite the multiple productivity demands, faculty that practice this career reflection, and model it for trainees, tend to be the most effective academic mentors, teachers, and clinicians.

Board Certification in Child and Adolescent Psychiatry

Original Certification

It is the RRC's responsibility to accredit training programs, but it is the ABPN that certifies individuals as competent to practice as specialists. The ABPN determines the accuracy of the applicant's credentials in regard to schooling and residency. To be a candidate for certification in child and adolescent psychiatry, one must have competently completed at least 3 postgraduate years of ACGME-approved residency in general psychiatry, including three clinical skills examinations on clinical interviewing skills; completed 2-year approved fellowship in child and adolescent psychiatry, including three clinical skills examinations with children and adolescents of at least two age groups, and one must have passed the ABPN examination in general psychiatry (16).

Maintenance of Certification

In 1995, the ABPN moved from an unlimited certification to a time-limited certification that requires recertification every 10 years. As posited by the ABMS, of which the ABPN is a member, each physician must engage in the process of maintenance of certification (MOC) that includes strategies that ensure a continuum of learning, self-assessment, professionalism, and cognitive growth through the MOC program. The ultimate goal is to assure the public of continued physician competence.

For child and adolescent psychiatry, MOC has four components: (1) professional standing, including holding an unrestricted medical license; (2) self-assessment and CME to enhance life-long learning; (3) cognitive performance, which includes passing a multiple-choice exam every 10 years; and (4) performance in practice (PIP)—one PIP unit per 3-year stage, which includes a chart-reviewed assessment of practice patterns. Beginning in 2016, a Patient Safety course is also required (16).

CHILD AND ADOLESCENT PSYCHIATRY TRAINING WITHIN BROADER MEDICAL EDUCATION

Medical Student Education in Child Psychiatry and Human Development

Lack of exposure to child and adolescent psychiatry has been identified as one of the major obstacles to recruitment into the field (1,19). Medical schools vary considerably in their curricula and in the utilization of their child and adolescent psychiatry faculty. Some schools have faculty contributing to required courses in

human development, but child psychiatry didactics are rare throughout medical school curricula. Most clerkships are heavily geared to teaching psychiatry in adult settings and medical students may receive few opportunities to see children and families—certainly not enough exposure in most schools to stimulate interest in the field (44). The Association of Directors of Medical Student Education in Psychiatry (ADMSEP) has developed a core group of child and adolescent psychiatry educators who are attempting to change this pattern, with recommendations and models of increasing medical student exposure to child psychiatry (45). Medical students who have an interest in development and in the psychosocial issues of children and families may choose elective opportunities in community settings, schools, child and adolescent inpatient or residential programs, or in clinical settings around the United States and abroad. There are many opportunities, but much has been relegated to the creativity of students and their mentors.

One important and innovative program is the Klingenstein Third Generation Foundation Fellowship (KTGF) in Child and Adolescent Psychiatry. Begun at Yale School of Medicine, the Klingenstein Fellowship serves to mentor interested medical students in child and adolescent psychiatry from their first year through graduation. The program has been replicated to currently include 14 programs nationally. Students accepted into the program are assigned a child and adolescent psychiatrist mentor based on their particular interests in the field. Students generally "shadow" faculty members in their work in a variety of clinical service areas. On a monthly basis, the students at each medical school spend an evening with faculty that may involve clinical discussions, movies, or didactic presentations. Additional opportunities for mentoring, observing clinical work, or doing elective academic projects, including engaging in research are encouraged (27). Annually, the programs meet to share experiences and collaborate in active learning and leisure activities.

The Continuum from Medical School through Residency Training

For residents who choose a traditional portal of entry into child and adolescent psychiatry and who did not have the good fortune of a KTGF or comparable fellowship experience, there is limited continuity in education and training from medical school through general psychiatry residency into child and adolescent psychiatry training. Most medical students interested in child and adolescent psychiatry have an interest in pediatrics. In fact, many struggle with the career decision between child psychiatry and pediatrics. Such students take many pediatric electives, though there may be few training opportunities in child psychiatry or the psychosocial aspects of pediatrics (44).

The general psychiatry residency requirement for child and adolescent psychiatry is for 2 months of clinical work with children and families. This may be done in

inpatient, partial hospital, or outpatient settings. General psychiatry residents may also take one of their two months of consultation psychiatry in child psychiatry and may take one of their two required months of neurology in pediatric neurology. In addition, the requirements for forensic and addictions may be completed with child and adolescent patients and 20% of outpatients may be youth. For residents interested in child and adolescent psychiatry early on, if their program offers the opportunity, they may be able to have considerable child psychiatry training before their child and adolescent psychiatry fellowship. For others, particularly the ones who discover child and adolescent psychiatry later in their generally psychiatry residency, there may be limited continuity between child and adolescent and general psychiatric residency training.

The Relationship between Child and Adolescent Psychiatry and Pediatrics

Collaborative Care Models

Pediatric residencies are required to teach 2 months of Developmental Behavioral Pediatrics within their 3 years of training. This is taught largely within pediatric programs themselves, although some may use affiliated child and adolescent psychiatry faculty to train their residents. All child and adolescent psychiatry programs have a formal rotation in consultation-liaison to pediatrics (34).

It is crucial for child and adolescent psychiatry and pediatric programs to develop and foster a close collaborative relationship. The Patient-Centered Medical Home, in which the primary care provider is the hub, and specialists, including child and adolescent psychiatrists, provide consultative services, is expected to proliferate under the Patient Protection and Affordable Care Act (46). This model of care is designed to improve access to care and integrate the full spectrum of health and mental health services to improve patient health outcomes. Additionally, the passage of the Mental Health Parity and Addiction Equity Act of 2008 (47), reflects the growing recognition of the legitimacy of mental illness as a health issue and societal acceptance of a principle of nondiscrimination in regard to the financing and provision of mental health services. The policy changes resulting from these statutes have set in motion a process of change in the healthcare system with significant implications for the professional role of child and adolescent psychiatrists—conferring a much more active role in the collaborative care environment (48,49). Child and adolescent psychiatry fellowship programs must anticipate these changes and begin to train the next generation of child and adolescent psychiatrists in the competencies required for optimal collaboration, consultation, and system-based practice within the patient-centered medical home setting (50,51). However, we must be sure not to “throw out the baby with the bath water.” As a relationship-based

specialty, child and adolescent psychiatry training programs must maintain an emphasis on therapeutic engagement and the healing attributes of the doctor–patient relationship.

SPECIAL ISSUES IN EDUCATION AND TRAINING: MENTORSHIP, MORALE, LEADERSHIP, LIFESTYLE, AND COMMUNITY

Professional Identity Formation: The Role of Mentors

Mentoring is frequently cited by trainees and early career psychiatrists as one of the most powerful influences in career development. Williams et al. (52), in a focus group study of mentor–mentee relationships, identified qualities that mentors and mentees should possess that facilitate good mentoring relationships. "Specifically, mentors must be compatible on a personal level, active listeners, able to identify potential strengths in their mentees, and able to assist mentees in defining and reaching goals. Mentees must be proactive, willing to learn, and be selective in accepting advice from their mentors." (p. 113)

Mentorship is an active process, which, when the key elements are present, may be a life-changing experience for both the mentor and the mentee. It is the power of the relationship that promotes development—the mentor's ability to envision in the mentee strengths, weaknesses, and growth potential—not just what he/she is at the time, but what he/she has the potential to become (53). Idealization of the mentee by the mentor and vice versa makes for a powerful bond. However, there is much more than idealization. Realistic appraisal, insight, motivation, and career expertise are other qualities of mentorship that are required to effectively assist the mentee in genuine growth.

Mentorship has been acknowledged as a crucial element of research careers, as demonstrated by the National Institutes of Health (NIH) Mentored Career Development Awards. However, mentorship may help launch clinical, administrative, teaching, and other career paths as well. Mentors may be assigned or developed on the basis of mutual identification in a less formal process. A study by Ragins and Cotton (54) suggests that informal mentored relationships, developed on the basis of mutual identification, led to greater benefits for protégés than formal arrangements. Formally arranged mentorship arrangements typically last between 6 months and 1 year (55); informal ones between 3 and 6 years (56). Martin (53) has noted that "it is less physical proximity than meaningful intellectual, personal, and emotional connections that count most" (p. 1226) in the mentor–mentee relationship. "More than duration, internalization can be seen as providing a useful metric for the success of the experience. Those individuals capable of invoking and making use of the other (whether spontaneously or through active effort) have been effectively

mentored." (p. 1228)

The risks inherent in the mentorship relationship are those that come with a power differential in a personal and intimate relationship. To be optimally successful, early and clear articulation of expectations of the work together in the mentorship relationship may provide the template and the scaffolding to build a relationship that launches a successful career. Frequent reassessment of the working relationship to ensure alignment of goals and expectations reinvigorates the work, and ensures the optimal effectiveness of the mentor–protégé bond. It is the sign of a successful mentorship relationship when the protégé becomes a mentor to others, thus rejuvenating and promulgating the transmission of values from generation to generation (53,55).

Physician Well-being: Promoting Resilience and Values in Our Students, Residents, and Faculty

While training departments may differ in their healthcare delivery system, the size and nature of the faculty, and in the population served, the core values and philosophy of child and adolescent psychiatry fellowship programs remain the same: We share a profound and passionate commitment to providing the highest standard of care for the children, adolescents, and families we serve. To optimally achieve this, departments must provide a culture in which students, residents, and faculty are treasured, where teaching is cherished, where deficiencies in individuals and in the program are sensitively remediated, and where deep trust and honest, open communication are shared and encouraged between all members of the community (57).

However, physician well-being and prevention of "burnout" is a very real concern. Physicians demonstrate higher rates of anxiety, depression, suicide, divorce, stress, and emotional exhaustion than other segments of the population (58). Burnout (emotional exhaustion, depersonalization, and feelings of worthlessness) results in poor patient care, poor self-care and physical health, diminished empathy, and medical errors (59). Morale may be diminished by many of the stresses facing modern healthcare systems: regulatory and managed care pressures; increasing faculty and fellow demands to provide clinical care and productivity demands; financial pressures and educational debt; and documentation requirements that may decrease time available to spend with children, families, and collaborators. All of these forces can breed demoralization among faculty and disappointment among the trainees, who in many institutions have had to shoulder increased caseloads and less direct supervision and mentoring. "These challenges are compounded by our profession's hidden curriculum—the reluctance to admit weakness, expose our shame of suffering from the stigma of a psychiatric disorder, or even discuss the pressures we share." (58) (p. 9)

How then can well-being, morale, and maintenance of the esteemed values of residency training and education be fostered? First and foremost, the PD must be fully aware of the service needs, administrative structures, and emotional climate within the institution and training sites. The PD needs to have a close working relationship with the director of GME, chair of the department, and division chief of child and adolescent psychiatry in order to make problems in the residency known and viewed as a priority. The ACGME has strengthened its mandates on the institution to provide support for the residency training mission, with monitoring via regular CLER. For serious issues related to the training program's learning environment, the medical school and/or hospital may be a source of needed resources. While the PD has no hiring or firing power over the faculty, he/she has significant authority, especially if his/her word is viewed by all as one with that of the Chair.

Beresin et al. (58) contend that, "State-of-the-art and well-evidenced education will impart not only medical knowledge but also a tool-box of coping skills…. The evidence needs to be marshaled to shift the hidden curriculum so that caring for oneself, maintaining cognitive and emotional acuity, and seeking fulfillment are considered professional obligations and preconditions for optimal patient outcomes" (p. 10). Improving physician well-being and satisfaction has been found to improve patients' satisfaction with the care they receive (57,60) . Table 1.4.3 provides suggestions to promote physician well-being.

TABLE 1.4.3

ACTIVITIES TO PROMOTE PHYSICIAN RESILIENCE AND WELL-BEING

1. Engagement activities to facilitate group cohesion:
   - Social or topic-related opportunities for relationship building
   - Retreats, meetings, conferences, with active listening and mutual feedback
   - Participation in small, process-oriented, longitudinal reflective seminars that discuss the emotional, physical, and social impacts of the practice of medicine
2. Ensure time in curriculum to discuss residency topics related to becoming an independently functioning physician:
   - Managing uncertainty and ambiguity
   - Caring for the difficult or hateful patient
   - Optimizing team functioning
   - Understanding medical errors and importance of apology
   - Discovering personal sources of renewal
   - Finding meaning in work
   - Fighting "burnout"
3. Skill building to become a reflective practitioner:
   - Practice writing and sharing reflective essays
   - Healthcare humanities book-clubs and readings
   - Mindfulness training
   - Participation in reflective seminars that discuss the emotional, physical, and social impacts of the practice of medicine
4. Curricular modules on Wellness:
   - Self-care, mindful meditation, and healthy lifestyle
   - Education about signs and symptoms of burnout and resources for professional help
5. Actively promote career and life goal setting:

- Self-reflective activities and discussions to assist with defining career-life priorities
- Facilitate specific opportunities—personal introductions to others in the field, nominating for committees, awards and fellowships, etc.
- Regularly acknowledge accomplishments, joys, sorrows, and personal value of each trainee

Faculty morale and well-being optimizes the learning environment for the fellows. Faculty that feel respected, valued, and connected to the mission of the department and the training program will improve the morale of the trainees and the institution. Frequent group and individual meetings of the PD with the teaching faculty are essential, as is being a direct conduit to the chief and chair. The PD may not be able to increase reimbursement for services or salaries, but can help the faculty in being recognized as key members of the academic program through providing and acknowledging educational contributions (e.g., teaching awards, notices of local and national presentations, and publications), and support of promotions. Regular faculty development workshops, retreats, and social gatherings are valuable ways to help foster a sense of group cohesion, even in times of increasing fragmentation. Most programs now have software for a common portal that allows for schedules, evaluations, and posting articles. These sites may serve a function of faculty engagement, in addition to information sharing.

Morale in a fellowship class is critical for the functioning of a training program. A class that is tight, supportive, smooth functioning, and just plain fun is instrumental to the personal and professional development of the residents. Fellows need the proper balance of supervision, mentoring, guidance, autonomy, time with each other, and time with friends and family. Morale is high when residents and faculty can truly say that they work hard, and play hard, and that they feel like family—and as in most families, there will be struggles and differences, but above all, unconditional love and support (58).

Teaching How to Teach: Leadership Development, Professional, and Public Education

The goal of child and adolescent psychiatry residency training is to train competent physicians and the next generation of leaders in the field. Integration of components of leadership training into the curriculum enhances this mission.

Graduates have identified lack of training in administrative, supervisory, and financial/managed care issues to be the areas of most deficiency in their training (61). Many child and adolescent psychiatrists are hired as team leaders and medical directors upon graduation. Thus, development of a high skill level in leadership, management, and teaching is needed in training.

Leaders may be defined as individuals who inspire others to go beyond what they think they are capable of doing, making it possible for a group to attain a goal that

was previously thought unattainable by (1) inspiring trust, (2) acting consistently, and (3) motivating with words and deeds.

Components of training in leadership skills and enhancing leadership potential may be categorized into six primary arenas: (1) value transmission and formation of an identity as a leader; (2) competency in core knowledge and skills; (3) effective listening, learning, and integrating skills; (4) promoting creativity; (5) effective communication and collaboration skills; and (6) promoting by words and actions sacrifice for the greater goal (62,63).

Programs have embedded components of leadership and management training to varying degrees. However, a more focused curriculum in leadership is needed. Teaching (public speaking skills, how to put together a presentation, making presentations more interactive, mentored teaching experiences), a high level of collaborative skills, team building, and a deep and abiding vision are required for truly effective leadership. Providing team leadership experiences, seminars on teaching, effective supervision and mentorship—all of these are curricular aspects of promoting leadership skills in trainees. Other components of a training curriculum to promote leadership development include interactive and experiential seminars on effective listening, learning and integrating, with constructive feedback on these skills by supervisors and others. A professional development seminar, working in and learning about systems, meeting creative leaders in the field to learn about their lives, career trajectories, motivations and advice, and ample elective time to explore areas of interest and promote creative projects are other options for promoting leadership within the residency training program. The options are numerous, and call on the creativity and resources of each program to individualize the professional development curriculum to the training mission of the institution.

Public education is a core professional responsibility of all physicians. Education begins in the office and hospital units with our patients, parents, and families. A parent and child need to understand principles of normal development and psychopathology and its treatment for a sound therapeutic alliance and effective collaboration with the physician. Child and adolescent psychiatrists are also frequently asked to speak at schools, religious organizations, and other community groups. Many of these talks help educate the public about normal development and its variations, as well as psychiatric problems and their treatment. Residencies are required to instruct residents in these patient-care–centered and public educational venues (34).

Research shows that Americans get much, if not most, of their mental health information from media news, including the Internet, and from public entertainment. Some programs perpetuate myths and misinformation. Others present controversial information that scares parents away from certain treatments. For example, the Federal Drug Administration’s black box warnings on certain antidepressants and stimulants frighten parents, are often misrepresented by certain groups in the media,

and cast doubt on some treatments frequently used by child and adolescent psychiatrists. Our residents and future practitioners need to be prepared to discuss these issues with patients and with the media. When used well, the many forms of mass and targeted media—including newspapers, radio, television, and the Internet—can counter inaccurate reports and destructive stereotypes. They can also provide information, reassurance, and perspective that can transform the lives of our patients and their families (64).

The expansion of mass media offers child and adolescent psychiatrists a new opportunity to influence public opinion and policy, and educate parents, teachers, and allied professionals who work with children and families. However, few residency programs prepare residents on how to interact with media. Residents benefit from seminars that help them appreciate the complex interests and motivations of journalists and how different forms of the mass media operate; learn ways of ordering priorities for public presentations as opposed to professional lectures and seminars; acquire specific skills needed for managing different forms of media and using mass media as an extension of their clinical practice; and have ample opportunity to practice these skills with teachers who have experience in interactions with the media (64,65).

Community in Education: The Role of Local, Regional, and National Organizations

Parker J. Palmer noted that "To teach is to create a space in which the community of truth is practiced" (66). Our community of truth is established by the close ties child and adolescent psychiatrists, pediatricians, and allied health professionals develop. Teaching requires a personal, inner commitment and devotion to our students, but cannot be separated from our community of practicing clinicians, researchers, educators, and administrators. How we establish "truth" is complex and communal. How we transmit, assess, and regulate the material of our field requires community. Sharing our research, empirical findings, clinical perspectives, standards of care, or educational models requires a community of professionals who are in continual dialogue. In this way, we advance child and adolescent psychiatry.

As our field moves more toward outcomes-based curricula, predicated on the acquisition of competencies, and as the attainment of knowledge, skills, and attitudes are viewed and assessed in a developmental context, we need ongoing collaboration between the national organizations that oversee educational programs. The Liaison Committee on Medical Education (LCME) and the Association of American Medical Colleges (AAMC), which oversee medical school education; the Accreditation Council for Continuing Medical Education (ACGME) and the ABMS, which oversee GME and certification; and the ABMS and the ACCME, which oversee continuing education and recertification, should actively work together to ensure that there is a

real continuum between all levels of medical education.

At local and regional levels, medical schools and residencies should share precious educational resources. Beyond exchanging teachers, examinations such as the "Mock Board" annual clinical exam could be shared between programs. Regional associations of our national organizations often have special events for medical students, residents, and faculty, and these enterprises should continue. It is not hard to offer mentors in a region for an interested medical student or resident. There are endless possibilities for developing and nurturing our educational community in child and adolescent psychiatry—for students, residents, faculty, and practicing clinicians. We must also not forget that our community has largely been confined to our medical schools and residencies. However, there are many allied professional schools, such as nursing, dental, public health, education, business, and law among others, that can prove invaluable by our facilitating cross-fertilization of students and faculty. Beyond this, an untapped resource in our local community is the university, with its undergraduate college and graduate schools of arts and sciences. Medicine has remained rather distant from these campuses. However, our faculty could provide excellent teaching for undergraduates, as is occurring in many colleges—including a minor in child and adolescent mental health studies (67). Further we are greatly underutilizing the many excellent faculty in the humanities, neuroscience, and social sciences that may make a new and important contribution to the training and education of our students and residents, while expanding and enriching our community of scholars.

Lifestyle Issues

Child and adolescent psychiatry, as one of the most underserved medical specialties, provides for a plethora of job opportunities for graduates. Child and adolescent psychiatry also fared extremely well in graduates' ratings of diversity of practice options, work–life balance, and flexibility (68).

Child and adolescent psychiatrists have widely diverse and varied practice options, including academics, research, clinical practice in a variety of settings (private practice, group practice, clinics, and within a continuum of care from outpatient, day treatment programs, residential treatment programs, and inpatient hospitalization). Consultations to schools, courts, hospitals, pediatric settings, and other agencies are common. Additionally, advocacy and public policy initiatives may be a formal or informal aspect of many child and adolescent psychiatry careers.

Child and adolescent psychiatry offers a unique opportunity to spend time with your patients and to watch them grow and develop over time and to their best potential. In a survey of early career child and adolescent psychiatrists, job satisfaction was rated very high overall—with a median overall career satisfaction rating of 5 on a 6-point Likert scale (13).

Lifestyle issues are being considered seriously by medical graduates when choosing a specialty. A carefully crafted career in child and adolescent psychiatry provides flexibility in work hours to allow a balance between career and family or other interests. Salaries are highly competitive. There are jobs in all parts of the country, allowing for geographic flexibility. Most institutions and agencies pay a higher salary to psychiatrists who have completed child and adolescent psychiatry training. According to 2016 survey data, the median income for child and adolescent psychiatrists was almost $200,000 (68,69).

Child and adolescent psychiatry remains a medical specialty with a serious shortage of physicians. However, the training and mentorship enterprise is thriving, with recruitment efforts starting from early in training. The superior training of the next generation of effective leaders in the field is the mission of PDs in child and adolescent psychiatry training programs. However, it "takes a village" to train a superior child and adolescent psychiatrist. Physicians, allied professionals, residency training coordinators, and patients and their families are all part of that village.

CHAPTER 1.5 ■ GLOBAL CHILD AND ADOLESCENT MENTAL HEALTH

MYRON L. BELFER, HESHAM M. HAMODA, AND MAURICE EISENBRUCH

GOAL

This chapter delineates areas of concern in global child and adolescent mental health and focuses on issues of particular clinical import to child and adolescent psychiatrists and other child mental health clinicians. Many of the topics that are addressed are now relevant to domestic practice given widespread global immigration patterns.

OVERVIEW

The concept of Global Mental Health is relatively recent embracing concerns for accessing evidence-based care, utilizing nonprofessional providers and engaging consumers. It should be noted that the concern for an international understanding of psychopathology in children goes back to the 1970s with seminal articles on child psychiatry in developing countries (1–3). As stated by Whitley (4) the origin can be traced back to 2007 when a series of articles in the *Lancet* discussed in detail the impact of mental health on health and well-being. The original articles did not address child and adolescent mental health concerns in a meaningful manner and it was not until 2011 that the *Lancet* published a comprehensive paper on global child and adolescent mental health (5). The various parties invested in global mental health established a Movement for Global Mental Health. The Movement and its associated initiatives have not been without some controversy. However, the goal to improve services for people living with mental health problems and psychosocial disabilities, particularly in low and middle income countries (LAMI) has brought about a global dialogue that has been beneficial in a number of ways. While the emphasis on global mental health has highlighted problems in access to care, diagnosis, and treatment more broadly it has been an ongoing challenge to have child mental health seen as a priority despite the overwhelming evidence of the early roots of mental illness and the impact of mental ill health on a host of social issues.

Global child and adolescent mental health embraces the world view on the place of children in society, the appreciation of diverse behavioral styles, the identification of psychopathology, and the setting of priorities for the use of scarce resources. Child and adolescent mental health is influenced by the economics of countries and societies within countries, by the internal and external displacement of children and adolescents through war and natural disasters, by the role of the child in the family,

and by the place of women in society. New knowledge and greater recognition of the impact on children of exposure to trauma, sexual and physical abuse, inhumane living and working situations, inadequate health care, and drug abuse have heightened interest in approaches to ameliorating the impact on child and adolescent health and mental health of these potentially pathogenic influences. It is a challenge to child and adolescent psychiatrists and allied professionals to be active participants in understanding the nature of the problems faced and in being a part of the solution (6).

The overall health and well-being of children are global concerns. All countries with the exception of the United States of America have ratified the 1989 United Nations Convention on the Rights of the Child (7,8). It commits countries to "ensure that all children have the right to develop physically and mentally to their full potential, to express their opinions freely, and to be protected against all forms of abuse and exploitation." The concern among some countries was the perception that ratification of the treaty would intrude on sovereign rights and/or traditional views of the child in a dependent position in society. In the end these concerns did not impede ratification but do impact implementation. In some countries that are party to the treaty, the affirmation of the rights of children has not resulted in benign policies toward the protection of children from harm or the fostering of positive development.

In the global arena, and increasingly in multicultural societies, child mental health and child psychopathology cannot be gauged solely from a Western perspective. It is simplistic to state, but meaningful to understand, that what may appear pathologic in one country or society, or to one cultural or subcultural group within a country, may be deemed normative or adaptive in another. This does not imply that it may not be helpful to have a consensus about a frame of reference regarding psychopathologic conditions, but the interested party must keep an open mind in attributing cause to behaviors, interpreting responses to events, or judging parental or familial interactions with children. The complexity of understanding children and adolescents embraces anthropologic, social, psychological, political, and rights dimensions. For the domestic practitioner, understanding the cultural context of the individual and family is important. For example, Murthy (9) reports that studies have found that suicide rates among immigrants are more closely aligned to the rates in the country of origin than to the rates in the country of adoption. Generally, suicide rates of immigrant populations are higher than in the country of origin. The methods of suicide are those used traditionally in the culture of origin. Canino et al. (10) also documented the persistence of the importance of culture-bound syndromes.

In many resource-poor countries, educational institutions represent the most coherent system for providing services to children and adolescents. As never before, the value placed on education in societies is being emphasized as agrarian pursuits have diminished in favor or more lucrative employment in other sectors or due to restrictive land policies. In resource-poor countries, the impact of technology is offering new opportunities but at the same time widening the gulf between rich and

poor, educated and uneducated. Urbanization combines with the technology revolution further to challenge accustomed ways that may stress individuals and families including the erosion of the extended family for support (11). Children and adolescents, as students or as part of a family, experience new stresses that convey either advantage or disadvantage, depending on access, intelligence, and resources. In response to these changes in society, resilience-building programs in schools, along with primary care health programs in communities, have evolved. While the emphasis on education may be profound in urban settings in resource-poor countries, the role of traditional healing for child mental health disorders, especially in rural settings, remains powerful (12–17). For instance, in Cambodia, the taxonomies and explanatory models of childhood illnesses are embedded in powerful beliefs about the role of ancestral spirits and the child's previous incarnation (18,19).

The role and responsibilities of child and adolescent psychiatrists and other child mental health professionals vary in resource-poor countries. The competencies of the child and adolescent psychiatrist must fit the needs of the society in which they exist (20,21). For example, epilepsy and intellectual disability clearly fall within the expected clinical competencies of child and adolescent psychiatrists in resource-poor countries but not in resource-rich countries. The infrastructure in some countries post conflict may have decimated the child mental health workforce. In Cambodia, for example, where the country's entire infrastructure, including the health system, was destroyed during the Khmer Rouge regime none of 43 surviving medical doctors in Cambodia were psychiatrists (22). When child psychiatry is a very scarce resource, there may be the opportunity for only a consultative role, limited diagnostics, and an inability to be part of or to stimulate discussion of national policy. Child and adolescent psychiatrists coming to resource-poor countries may play a vital role in educating others but must be willing to increase their cultural competence, self-reflection and in this way to increase their mindfulness of the local cultural context, inherent capacity of the existing systems, and ways to ensure the provision of appropriate education. "Dropping in" to provide Western-oriented psychiatric education or consultation may do more harm than good.

In understanding the impact of child and adolescent psychiatric disorders, it is not sufficient to understand diagnosis alone. Significant gains have been made in raising the consciousness about the mental health of children and adolescents, as well as adults, by bringing attention to the "burden" of mental illness (23). The global burden of disease is now most often measured in disability-adjusted life-years (DALYs). This approach makes possible a more standardized assessment of the burden of disease as measured by lost opportunity, diminished function, and the cost of treatment and rehabilitation, and it has gained a supportive response from policymakers. From the child mental health perspective, DALYs have limitations in that they do not quantify negative or positive effects of behaviors but only address outcomes. As a result, the importance of behaviors that start during childhood and

adolescence but result in disease and death only later in life may be underestimated by this approach.

While global partnerships and international collaboration is essential in advancing child mental health, efforts in this regard are still in their infancy. Hamoda and Belfer (24) note that the global health scene, including that of global child mental health is characterized by fragmentation, lack of coordination, and even confusion. Many global health initiatives have been criticized as being narrowly focused on specific diseases rather than systems-wide strengthening, tend to be "top-down" in nature and are largely driven by donor agendas rather than the country's own needs and priorities (25). Many of the initiatives also lack mechanisms of accountability, transparency, and evaluation (26).

CONTEXTUAL CONCERNS ASSOCIATED WITH MENTAL DYSFUNCTION

Displacement

The global problem of displacement from family, home, community, and country are of enormous importance to the mental health of populations. Displacement by war resulted in approximately 60 million refugees, and displaced people in 2015 many of whom are children and women (27). Fullilove (28) emphasizes the importance of "place" in the healthy development of individuals and clearly the displacement resulting from war, ethnic conflict, and famine undermine the ability to establish "place." Sampson et al. (29) specifically address the importance of the community as a mitigating influence on violence impacting children and adolescents. "Collective efficacy" and individual "agency" in communities are important concepts when one considers the impact of imposed poverty, housing disruption, and displacement in ethnic conflicts affecting previously closely aligned groups. In resource-poor countries, the notion of "place" and community are of equal or greater importance. Forced emigration and the loss of parents and relatives in war often mean abandonment or orphaning of children and adolescents. Although these stressors may serve to demonstrate the enormous resiliency of youth it must be recognized that there are significant psychological consequences that can lead to depression, suicide, and a range of stress responses that require informed intervention.

The problems of displacement from homes, families, communities, and countries affect children in a host of ways. Zivcic' (30), in a study of Croatian children during war, found significantly higher depressive and phobic symptoms in displaced refugee children than in local children in stable social conditions. Laor et al. (31), in a developmental study of Israeli children exposed to Scud missile attacks, found higher externalizing and stress symptoms in displaced children as opposed to those able to maintain family and community connections. Children in these circumstances may

find themselves without the protection and support of parents at critical junctures in their lives. Children are forced to act in more mature ways far earlier than normal development would dictate or allow. Displaced children are faced with exposure to war and violence that may have included seeing family members murdered. Less often, but even more horrific, some children have been forced into being the murderers of their family or conscripted to serve as child soldiers. Displaced children who need to survive on urban streets engage in survival tactics that include criminal activity and prostitution. In an effort to find a context for survival, the formation of youth gangs is increasingly evident, especially in societies where there is a lapse in government organization and control. More often than not, the children are the victims rather than the perpetrators.

Many refugees live in camps that have become “total institutions” with the attendant “process of mortification” (32). Dependency is a feature in many camps and especially in those that reproduce the authoritarian regimes from which the refugees escaped (33). Others are suffering from the multiple traumatic effects of torture. An outbreak of peace may mean fewer violent deaths, but entering the repatriation and resettlement phase of the cycle is yet another challenge for the disempowered (34,35).

Children Exposed to Conflict

The priority concern of global child and adolescent mental health is often the acute and continuing tragedies that involve youth in armed conflict or its aftermath. Eighty percent of the victims of war are reported to be children and women (36). The result of armed conflict is often displacement externally as refugees or asylum seekers or internally within settings of civil war. Thabet and Vostanis (37) investigated anxiety symptoms and disorders in children living in the Gaza strip and their relation to social adversities. Children reported high rates of significant anxiety problems and teachers reported high rates of mental health problems that would justify clinical assessment. Anxiety problems, particularly negative cognitions, increased with age and were significantly higher among girls. Low socioeconomic status (father unemployed or unskilled worker) was the strongest predictor of general mental health problems. Living in inner city areas or camps, both common among refugees, was strongly associated with anxiety problems. Among Syrian refugees displaced internally or as refugees more than half are children, and of these, nearly 75% are less than 12 years old (38).

Thabet et al. (39) examined the mental health profile among 322 Arab children living in the Gaza strip. Western categories of mental health problems did not clearly emerge from the factor analysis, the main difference appearing to operate in parents’ perceptions of emotional problems in preschool children. The authors warn of the need to establish indigenously meaningful constructs within this population and

culture, and subsequently revise measures of child mental health problems.

More attention is needed to culturally appropriate trauma therapy for children. Culture mediates the possible range of child responses (40). In older studies more than half of children exposed to war meet the criteria of posttraumatic stress disorder (PTSD) (41). With more experience the need to be cautious about the diagnosis of PTSD in children has emerged. Anxiety and depression are the disorders of primary concern. Symptoms should not be mistaken for disorders. Panter-Brick et al. (42) showed in her study of children exposed to war and violence in Afghanistan that the overwhelming concern of children even when witnessing death was the day-to-day anxieties associated with family issues, school, and peers. Cartwright et al. (43) found that among a sample of Syrian refugee children in Turkey nearly half had clinically significant levels of anxiety or withdrawal, and almost two thirds were fearful. Several reports (44–47) have shown a variety of psychosocial difficulties among Syrian refugee children including insomnia, sadness, grieving and depression, aggression and behavioral problems, nervousness, regression, hyperactivity, speech problems, and somatic symptoms.

"Child Soldiers" and Exploitation of Children

In the turmoil of some resource-poor countries, children are now being forced to become child soldiers, and others are drawn into the conflict as sexual slaves. Child soldiers reportedly suffer PTSD (48–53). Somasundaram states that to prevent children becoming soldiers we need first to understand why children choose to fight due to push factors (traumatization, brutalization, deprivation, institutionalized violence, and sociocultural factors) and pull factors (military drill from early childhood), as well as society's complicity (54).

These horrific experiences place an as yet undefined burden on the psychological development of the victim. Understanding these experiences may shed additional light on the extremes to which resiliency may allow future healthy development, but perhaps more likely it will demonstrate the more permanent scarring evidenced in disturbed interpersonal relationships, distorted defenses, heightened aggression, reduced empathy, and self-destructive behavior. The data are not yet available to ascertain whether these young people evidence PTSD in the classic sense or whether, because of the early age of induction into the culture of war, they develop in a different way as a survival response. Huge challenges face child mental health clinicians in helping to reclaim the lives of former child soldiers (55,56).

As for trafficking in children, worldwide, in 2015 an estimated 1.2 million children are forced into prostitution or trafficked every year and the total number of prostituted children could be as high as 10 million (57). Children are trafficked worldwide (58–66). The most urgent attention is paid to combating the trafficking (67), but the management of the psychological sequelae for the children will need to

be given further attention. Nongovernmental organizations have been taking a lead in developing programs for children and adolescents freed from trafficking. Another issue of concern is the trafficking of children for child labor and other forms of exploitation. The International Labor Organization has taken this up as a major concern (68). The psychological consequences of child labor are complex, involving distorted relationships of children to their families and the assumption of adult roles prematurely.

HIV/AIDS

In sub-Saharan Africa, Russia, and parts of Asia, acquired immunodeficiency syndrome (AIDS) continues to be a major health concern (69). As documented by Carlson and Earls (70), whether through social policy as evidenced in the Leagane children of Romania, or as the consequence of the pandemic of AIDS, the rearing of children in orphanages or in other situations that deprive children of appropriate stimulation and nurturance has potentially long-lasting consequences for societies. Those infected but struggling with the illness face the prospect of having to adjust to declining physical and mental functioning and often living isolated lives. Thus, the mental health consequences of AIDS as a chronic and pervasive illness must be considered. There is the obvious concern with the direct effect of AIDS on the youth with manifestations of neuropsychological dysfunction including dementia, depression, and other disorders, which go largely untreated. Access to antiretroviral drugs is often denied or difficult to access due to economic or discriminatory policies. Special attention needs to be given to the consequences of AIDS on children and youth. The direct impact on children and adolescents is evident in India, other parts of Asia, and Africa, where sexual exploitation has led to a high incidence of youth infected. With wider use of antiretroviral medications the challenge has shifted to provide for a healthy living environment for those who are often discriminated against.

Substance Abuse

Substance abuse in children and adolescents is a worldwide problem (71). In resource-poor countries, the problem is of no less importance than in Western countries and exacts a tremendous toll in terms of morbidity and mortality. Illicit drugs and psychoactive substances not defined as drugs of abuse (such as khat, inhalants, and alcohol) are used by youth regardless of economic circumstance or religious prohibition. Risk factors, while sharing features in common, vary by cultural context, for example in Turkey (72) or Lebanon (73). Due to prohibition in some Muslim countries official data on alcohol use and abuse is very limited. Remarkably in some Muslim countries, alcohol use and abuse are significant

contributors to psychological morbidity (74). Khat or miraa (Catha edulis) is used extensively in East Africa and the Middle East. In Somalia, Ethiopia, and Kenya, the leaves of khat are chewed at all levels of society from about the age of 10 (75). Khat may induce a mild euphoria and excitement that can progress to hypomania. In youth, khat use, especially if it is combined with the use of other psychoactive substances, may lead to psychosis.

Homeless street children are now found worldwide and appear particularly vulnerable to substance abuse and other high-risk behavior (76). Senanayake et al. (77) studied the background, life styles, health, and prevalence of abuse of street children in Colombo. Family disintegration was mentioned as the cause for life on the streets by 36%; child labor was reported in 38%; 16% admitted to being sexually abused; 20% were tobacco smokers. Homeless children also are prominent among those groups using inhalants and who are caught in cycles of physical and sexual abuse, often under the influence of drugs. Road accidents among those using drugs are also high.

Solvent and inhalant use is associated with poor economies. In South America, inhalant use is a dominant factor in the presentation of youth affected by psychoactive substances. In São Paolo, Brazil it is reported that up to 25% of children age 9 to 18 years abuse solvents (78). In the Sudan, gasoline is the inhalant of choice, whereas in Mexico, Brazil, and elsewhere in Latin America, paint thinner, plastic cement, shoe dye, and industrial glue are often used. Solvent use is also found among the aboriginal groups in Australia and on Native Canadian reservations (79). In Mexico, 3 of every 1,000 people between the ages of 14 and 24 years use inhalants on a regular basis (80). These figures do not include two high-risk groups, the homeless population and those less than 14 years old, whose rates of inhalant abuse are much greater. Several community studies carried out in different parts of Mexico show that starting ages are as young as 5 or 6 years (80). Data suggest that the percentage of young people using inhalants decreases with age, as other substances such as alcohol and marijuana are substituted. Inhalant use decreases as educational level increases (81).

Wittig et al. (82) examine the hypothesis that drug use among Honduran street children is a function of developmental social isolation from cultural and structural influences. Data from 1,244 children working and/or living on the streets of Tegucigalpa are described, separating “market” from “street” children. The latter group is then divided into those who sniff glue and those who do not to identify salient distinguishing factors. Family relations, length of time on the street, and delinquency are the most important factors.

Forster et al. (83) studied the self-reported activities engaged in by children found wandering on the streets of Porto Alegre, Brazil, aiming to describe their drug abuse habits and practice of thefts or mendicancy. Regular abuse of inhalants was reported much more frequently by the street subgroup of children, reaching a prevalence of

40%. The practice of theft was self-reported mainly by the children from the street group and only by the ones who used illicit drugs. These results show that very poor children might spend many hours of the day by themselves in the streets of a big city accompanied by children who are never under adult supervision. In spite of being alone for some hours a day and making friends with others who might use drugs, having a family and regularly attending school decreases the risk of delinquent acts and drug use.

Violence and Abuse

Violence to and by children and adolescents now appears to be all too prevalent worldwide (84). Bullying, corporal punishment, victimization of parents by children and adolescents has now been reported worldwide. It is beyond the scope of this chapter to address all forms of violence; it will focus on specifics related to child abuse. Understanding child abuse requires understanding the vast cultural diversity in which children and adolescents live, and there is a need for greater attention to be given to possible country-specific interventions (85). What is termed abuse varies between cultures.

There are differences in cross-cultural definitions, incidence in developed and developing countries across continents, and measures that have been instituted to prevent and manage child maltreatment (86). The literature suggests that child maltreatment is less likely in countries in which children are highly valued for their economic utility, for perpetuating family lines, and as sources of emotional pleasure and satisfaction. However, even in societies that value children, some children are valued more than others (87). Ethnicity has been found to play a role in the epidemiology of pediatric injury (88). There is a diverse culture-specific literature on abuse (89–91).

There are reports of structural models of the determinants of harsh parenting, for example, among Mexican mothers, where cultural beliefs play a major role in parenting within the framework of Mexican family relations (92). Changing cultural norms and attitudes in a given setting (e.g., Korea) can lead to children being at risk of abuse in the name of discipline or other seemingly appropriate parental or authority responses (93–95). Child abuse might increase in certain cultural groups as a result of cultural change rather than emerging from their traditions (96). Child psychiatrists with insufficient awareness about normative practices by parents, for example, dermabrasion or cao gao in Vietnam (97), may jump to the conclusion that hematomas around the child's head, neck, or chest signal that the parents may have been wrongdoers who abused their child. A culturally competent child psychiatrist, while not dismissing abuse out of hand, would also evaluate the alternative possibility, that the parents, with the best interests of the child in mind, submitted him/her to ritual treatment, for which the bruising acts as a public signal to the

community that the child has been unwell.

Shalhoub-Kevorkian (98) reported a survey of victims of sexual abuse among Palestinian Israeli girls aged 14 to 16 years. Data revealed that the girls' attitudes not only conformed to general findings on disclosure of sexual abuse but also reflected sociopolitical fears and stressors. Helpers struggled between their beliefs that they should abide by the state's formal legal policies and their consideration of the victim's context. The study reveals how decontextualizing child protection laws and policies can keep sexually abused girls from seeking help.

The legal implications of child abuse are affected by practices which may be normative in certain cultural settings, for example, female genital mutilation (99). Some ethnic groups may carry out procedures on their children as a sign of caring rather than as a punitive measure. For instance in Cambodian and Vietnam there are cases with facial burns associated with what was termed "innocent cultural belief" (100). Thus, factors that lead to underreporting by physicians have included ethnic and cultural issues (101). Ethnographic data point to the importance of the social fabric in accounting for differences in child maltreatment report rates by predominant neighborhood ethnicity (102). There can be mismatches between the definition of child abuse between the culture of the professional and the culture of the families (103). There is much to be learned about the use of cultural evidence in child maltreatment law (104).

Case Illustration

Child abuse is subject to the definitions of various audiences rather than being intrinsic to the act. There are a few studies concerning the effect of culture and context of the professionals (as opposed to the families)—as in a study of Palestinian health/social workers where people agreed on what was child abuse but disagreed on when it should be reported. The results indicated a high level of agreement among students in viewing situations of abuse as well as neglect as maltreatment. Differences were found in their willingness to report situations of maltreatment. An inclination was found among students to minimize social and cultural factors as risk factors and to disregard signs that did not contain explicit signals of danger as characteristics of maltreated children (105). Baker and Dwairy (106) examined intervention in sexual abuse cases among the Palestinian community in Israel. They suggest that in many collective societies people live in interdependence with their families. Enforcing the laws against sexual perpetrators typically threatens the unity and reputation of the family, and therefore this option is rejected and the family turns against the victim. Instead of punishing the perpetrator, families often protect him and blame the victim. The punishment of the abuser results in the re-victimization of the abused since the family possesses authority. Baker and Dwairy (106) suggest a culturally sensitive model of intervention that includes a condemning, apologizing,

and punishing ceremony. In this way, exploiting the power of the family for the benefit of the victim of abuse before enforcing the law may achieve the same legal objectives as state intervention, without threatening the reputation and the unity of the family, and therefore save the victim from harm.

TAXONOMY AND CLASSIFICATION

Munir and Beardslee (107) are critical of DSM approaches and propose a developmental and psychobiologic framework for understanding the role of culture in child and adolescent psychiatry. Kriegler (108), taking a social constructivist perspective on the potential relevance of DSM-5 disorders for South African children and youth, regarding PTSD and attention deficit hyperactivity disorder (ADHD), demonstrates that these psychiatric labels are impracticable and irrelevant in a postcolonial developing country, where mental health care is delivered in the context of scarce services and unequal access. Beauchaine (109) notes that developmental psychopathologists have criticized categorical classification systems for their inability to account for within-generation heterogeneity in cultural influences on behavior. Novins et al. (110) attempted cultural case formulations for four American Indian children and identified several gaps concerning cultural identity and cultural elements of the therapeutic relationship.

Culture and Assessment

There has been a growing recognition in child psychiatry in Western settings to consider cultural context in the assessment of psychopathology (10). A culturally competent framework for assessment in resource-poor countries, while sorely needed, has not been developed. A simplistic attribution to culture of seemingly bizarre symptoms that in fact represent treatable mental illness would deflect energy from the development of effective treatment and prevention efforts. At the same time, an understanding of the cultural construction of major psychiatric disorders (including culture-bound disorders affecting young people) would minimize inaccurate diagnoses. This view has to be balanced with the understanding of less severe psychopathology, in which the observation of Neki (111) holds true, that ethnodynamics determine psychodynamics. In India, where the cultural ideal of an independent adult is not an autonomous adult, dependency is inculcated from childhood through a prolonged dependency relationship between mother and child. Dependency has a negative, pejorative connotation in Western thought, which is not so in the Indian context. The fostering of dependency is coupled with a high degree of control, low autonomy, and strict discipline, enforced within the broad framework of the family system. When this is identified by clinicians as representing a degree of pathology, decreased emphasis on the expression of thoughts and emotions in

children could explain the greater preponderance of neurotic, psychosomatic, and somatization disorders (112). Thus, cultural context influences the definition of normalcy or disorder. It proscribes the values and ideals for the behavior of individuals, it determines the threshold of acceptance of pathology, and it provides guidelines for the handling of pathology and its correction (113).

Cultural issues also affect assessment because of problems with cultural validation of instruments. A German study showed problems in applying the United States factor structure of the Conners Parent Rating Scale (CPRS), with lack of correspondence of the impulsiveness/hyperactivity scale (114). The factor structure of scores of the CPRS has been examined among Nepali children (115). A Greek study of the Conners-28 teacher questionnaire in a Greek community sample of primary schoolchildren found that the factor structure was similar to that originally reported by the United States, with a high level of discrimination between the referred and nonreferred sample, especially for the inattentive-passive scale (116).

Rey et al. (117) noted the lack of simple, reliable measures of the quality of the environment in which a child was reared which could be used in clinical research and practice. They developed a global scale to appraise retrospectively the quality of that environment and found good interrater reliability with clinicians from Australia, Hong Kong, and the People's Republic of China. Goodman et al. (118) developed a computerized algorithm to predict child psychiatric diagnoses on the basis of the symptom and impact scores derived from Strengths and Difficulties Questionnaire (SDQ) completed by parents, teachers, and young people. The predictive algorithm generates ratings for conduct disorders, emotional disorders, hyperactivity disorders, and any psychiatric disorder. The algorithm was applied to patients attending child mental health clinics in Britain and Bangladesh. SDQ prediction for any given disorder correctly identified 81% to 91% of the children who had that diagnosis.

Epidemiology

Determining the epidemiology of childhood mental disorders in Western society is a challenge. On the international scene, the ability to determine the precise magnitude of mental disorders is even more complex. Reporting systems are inadequate, the definition or recognition of disorders varies or has variable interpretations, and the cultural component of what constitutes a disorder is only now being more fully appreciated by epidemiologists and researchers. Of significance in resource-poor countries is that any measure of mental disorder takes place against a background of child and adolescent mortality and morbidity that makes the epidemiology of psychiatric disorder is not only inaccurate, but often of a lower priority. Thus, in studying the epidemiology of psychiatric disorder in children and adolescents in resource-poor countries, it is important to define not only the prevalence and incidence of the disorders, but also the degree of impairment and burden of disease.

No single study or consistent set of independent studies on the epidemiology of child and adolescent disorders since 1980 can be identified as definitive or relevant across societies. Those studies carried out in the 1980s reflect the deficiencies noted earlier and certainly do not reflect the current realities of the countries from which the data were reported (119,120). Weiss has defined a new epidemiological approach combining qualitative study with classic epidemiologic methods (121–123). This new “cultural epidemiologic” approach has not yet been applied to child and adolescent mental disorders but holds the promise of gaining a more satisfactory understanding of the nature and extent of child and adolescent mental disorders worldwide.

Until now, when one has been faced with the realities of resource-poor countries, as noted, there is the danger of becoming a diagnostic nihilist in attempting to understand mental disorders in youth. However, for example, responsible investigators in Western Ethiopia clearly identified disordered mental functioning that meets a set of defined criteria (124). There is clear evidence that depression, psychosis, and mania can be defined and treated. The problem arises when one considers the context for the presentation of child and adolescent mental disorders. Is a hallucination during a ritual a disturbance in need of treatment? If the hallucination persists, should it be treated? What diagnostic label is appropriate? Giel and Van Luijk (125) found, in the pre-HIV/AIDS era, and counter to prevailing belief, that mental disorders were diagnosed more frequently than infectious diseases in the health centers in Africa that they studied. Until reporting is adequate and accurate, it cannot be assumed that the current state of mental health in the developing world actually supports the too prevalent minimalist and optimistic view. This sense is supported by the finding from WHO studies of primary care clinicians that showed that many patients seeking care had mental disorders, and their communities were aware of the problem (126). In the current era, Omigbodun (127) documented the psychosocial problems in a child and adolescent psychiatric clinic population in Nigeria: 62.2% of new referrals to the clinic had significant psychosocial stressors in the year preceding presentation. Problems with primary support, such as separation from parents to live with relatives, disruption of the family, abandonment by the mother, psychiatric illness in a parent, and sexual/physical abuse occurred in 39.4%. Significantly more children and adolescents with disruptive behavior disorders and disorders like enuresis, separation anxiety, and suicidal behavior had psychosocial stressors when compared to children with psychotic conditions, autistic disorder, and epilepsy.

Prevalence

Although it is interesting to consider epidemiological reports of more esoteric disorders, these are a distraction from the significant burden of disease that needs to

be addressed in the mainstream of care. In most studies, the methodological inadequacies and other constraints do not permit these studies to be of use for program planning nor needs assessment. However, most countries today have access to appropriate epidemiologic study guidelines, and it is a matter of setting a national priority and allocating resources to ascertain the data.

What of the disorders that now occupy considerable attention in developed countries such as ADHD, autism, and anorexia nervosa? The diagnosis and treatment of these disorders highlight both weakness and strength of having an international perspective. The recognition and labeling of disorders come as a result of improved international communication. However, the process of assessment must take into account a host of cultural as well as formal diagnostic criteria, and this is too often ignored. Cultural concepts of what is normal or abnormal and how parents perceive the presence or absence of a diagnosable disorder are essential to consider (128). In the case of eating disorders, there is clear evidence that the incidence may be affected by Western influences (129). In the diagnosis of ADHD pharmaceutical companies are now a primary source of both public and professional education and they often focus on the use of the diagnosis for the purpose of implementing a pharmacological intervention. This trend may provide an indirect incentive for the overdiagnosis of disorders such as ADHD and bipolar disorder. The understanding of the influence of increased public education on diagnosis requires further study (130).

Fayyad et al. (131), discussing the development of systems of care in resource-poor countries, focuses on ADHD and the development of a comprehensive system of care around it in Lebanon. In a study of adolescents in Bahrain diagnosed with adjustment disorder, al-Ansari and Matar (132) examined the type of life stressors that initiated their referrals to a child psychiatry unit. Disappointment in relationships with a family member or with a friend of the opposite sex was found to be the main stressor. Eating disorders classically are rare in resource-poor countries such as India (133), but anecdotal evidence suggests that with globalization and migration the rates are increasing (134–137). Autism is reported around the world, including in resource-poor countries (138–140), and with a cross-national consistency (141,142).

Specific Mental Disorders

In an earlier version of this chapter considerable attention was devoted to individual mental disorders as seen in countries around the world. It is now evident that with comparable methodologies there is little variation between countries in terms of formal diagnoses. Giel et al. (128) demonstrated in four countries (Sudan, Philippines, Colombia, and India) that between 12% and 29% of children aged 5 to 15 years showed mental health problems. The types of disorder identified in these resource-poor countries were reported as being no different from those encountered

in industrialized countries. Thabet and Vostanis (37) state that their findings do not support the commonly held belief that in non-Western societies anxiety and other mental health symptoms are predominantly expressed through somatizing symptoms. Citing Nikapota, Thabet and Vostanis (37) state that child mental health symptoms do not differ significantly across cultures and culture-specific mental health disorders are rare. A cross-cultural evaluation of depression in children in Egypt, Kuwait, and the United States showed similar clinical patterns (143).

More important is an understanding that the current diagnostic nomenclatures are limited in given full expression to the nature of distress and the degree of impairment experienced. Furthermore, considerable attention needs to be paid to specific cultural overlays on the disorders seen. Developing countries give added insight to understanding the importance of considering dimensional as opposed to categorical diagnoses.

The impact of "big pharma" in developing countries—which has been called "Bad Pharma, Bad Karma" (144) has often skewed the assessment of the true prevalence of disorders and influenced the diagnoses of disorders. There needs to be a balance between an understanding of the beneficial effects of medication and the need to provide "rational" care, that is, the use of psychosocial treatments as a first line of care.

Of concern is the implementation of clinical interventions that may inadvertently lead to an exacerbation or prolongation of symptoms: For example, the use of "ventilation" and retelling of the trauma through various means has been shown to have negative effects (145), whereas reestablishing families and returning to normal routines, including school attendance, has a salutary impact.

Suicide

Suicide in youth is a pervasive world mental health problem. In Western cultures, suicide is overwhelmingly associated with defined mental illness. Suicide is the second leading cause of death for American Indian and Alaska Native youth (146). Elsewhere in the world, it may be very difficult to identify the mental illness associated with the suicidal act—and in the face of overwhelming helplessness; suicide may appear from the perspective of the protagonists as the only way out, with no clearly labeled mental illness. Doing qualitative research on suicide in a developing country poses special challenges (147). Studies of suicide in the West have focused on risk factors associated with cognitive distortions, substance use, and familial factors (148). In trying to assess the high rates of suicide in some resource-poor countries, it appears that the balance in determining suicidal risk may rest with environmental stressors and the perception of no way out. Expectations may often be more determinant of suicidal angst than reality (149). According to one view expressed by Murthy (150), the traditional protective effect of religion in certain

cultures seems not to operate among the younger generation.

Chan et al. (151) consider suicide in China as a response to change due to globalization, in which Chinese values are more closely identified with the global culture. The high suicide rate is thus not seen as a reflection of psychiatric disorder but of sociocultural factors. It seems more apparent that suicide is viewed by those without demonstrable mental illness as a solution to social and personal dilemmas that bring with them thwarted expectations for a happy or successful life. For example, from this perspective, in India and in other resource-poor countries, the focus of the suicidal individual is not on achieving some exalted goal, but on being able to have enough of a dowry to be married, to not be isolated because of rape, or to be successful in passing a school advancement examination. This relative alteration in emphasis is important in the consideration of intervention strategies and in the training of workers to perform triage and to treat suicidal children and adolescents. A survey of adolescent health in nine Caribbean countries identified risk and protective factors predisposing to suicide attempts (152). In Hong Kong, amid the impressive high-rise buildings and fancy stores, reside families barely able to subsist. In this context of economic hardship, the result in part of massive economic adjustment in the Far East, the phenomenon of family suicide exists. Chan reports that families come together and, in a well-planned manner, seal themselves in their small apartments and light a charcoal heater (153). In a relatively brief time, the members of the family are asphyxiated. This has become an acceptable form of suicide in that the bodies remain intact and have an attractive appearance because of the monoxide poisoning. To the extent that it has been possible to determine the psychological state of the family before the suicides, major psychiatric disturbance has not been reported.

In a review Lester (154) notes that suicide rates have been reported to be lower in Muslims than in those of other religions even in countries that have populations belonging to several religious groups. However, rates of attempted suicide, on the other hand, do not appear to be lower in Muslims as compared to non-Muslims. The reports of suicide being lower in Muslim countries has been challenged though by the notion that suicide has been poorly studied in these countries and that some Muslim countries do not collect such data and/or do not report them to the WHO (155). Similar questions have also been raised about lower suicide rates in Catholic countries. Kelleher et al. (156) note that the average reported rates of suicide for countries with religious sanctions are lower than those for countries without religious sanctions. However, recording and reporting for those countries may be affected by the existence of sanctions, thus diminishing the reliability of reported rates.

Case Illustration

In India, four sisters aged 16 to 24 years committed suicide by hanging after an

evening during which they bought sweet cakes and samosas and played word games. The context was that they were part of a once prosperous family in which the father died of tuberculosis for lack of medical treatment. Now they were periodically without sufficient food, but with a mother too proud to ask for help. This family was socially isolated because of parental marriage across religious lines, and they had suffered an unexpected financial downturn as a result of a road-widening project that took their once-fertile land. Suicide rates in India, although lower than the international average of 16 per 100,000, have been steadily rising. Psychiatrists believe this is in part a result of the accelerating pace of social and economic change. Whereas the biggest risk factor in the West is mental illness, studies in India have consistently found that the dominant risk factor is a combination of social and economic strain. Farmers in debt may take pesticide, and ostracized women who are victims of the dowry system in economically stretched circumstances might immolate themselves (157).

Disabilities, Intellectual Disability, and Epilepsy

Disability—whether physical or mental—is all too common in resource-poor countries, especially those post conflict. In Cambodia, for example, between 2% and 3% of the population, or about 1 out of every 40 Cambodians, have physical disabilities (including 50,000 landmine survivors, many of them young people; 60,000 with paralysis from polio; 100,000 who are blind; 120,000 who are deaf; 102,000 to 178,500 with intellectual disability; 20,400 to 40,800 people with severe mental disorders; and 154,000 to 408,000 people with epilepsy) (158,159).

Intellectual disability and epilepsy are major disorders that often dominate the services of child mental health and pediatric professionals in resource-poor countries. Intellectual disability and epilepsy are the most common mental disorders in India (160). The rate of serious intellectual disability in some resource-poor countries ranges from 5 to 16.2 per 1,000 population (161,162), significantly higher than the rate in the West. Cerebral palsy and postnatal causes of intellectual disability are much more common in transitional societies than in developed countries. Untreated epilepsy limits a person's potential to participate in society. Unfortunately, although the cost of medication is relatively low, access to care is often limited. The care of the intellectually disabled varies widely in resource-poor countries. In some countries, special effort is made to provide for productive lives with meaningful vocational education, especially in agrarian economies. All too often, the moderately and severely retarded are housed in minimal care institutions where premature death and illness are common.

Kim and Kumar (163) describe Dohsa-hou as a Japanese psychological rehabilitation method widely used in Japan for children with intellectual disability, cerebral palsy, and autism. The focus is to improve bodily movements and posture as

well as to introduce social support to patients and their first-degree relatives. Analysis showed mothers got more social support interacting with their child's trainer and supervisor during Dohsa-hou. Trainers were more interactive than mothers in the Indian group, followed by the Japanese and Korean cultural groups.

Children with disability such as epilepsy are among the most marginalized in many resource-poor countries. In Cambodia, for example, they have limited access to education, vocational training, employment, and income-generating opportunities and other services. Childhood epilepsy is viewed traditionally as caused by the attack of the preceding mother from the previous incarnation of the infant, and treatment may be sought by parents from kruu, or traditional healers, to ward off her attacks. The children may be cared for in the Buddhist temple, or kept indoors out of the sight of neighbors.

SERVICES

The World Health Organization (WHO), through the Atlas project, has developed the first objective profile of resources for services related to child and adolescent mental health (164). The findings confirm the worldwide gap in services to address child and adolescent mental health (165); the gaps exist in both resource-poor and resource-rich countries. The lack of services is tied to insufficient and unstable financing, lack of trained professionals, and lack of policy to support the development of child and adolescent mental health services.

Resource-poor countries lack the child mental health personnel to mount large-scale programs of treatment with fully trained staff members. The prospect of training large numbers of child mental health workers remains a continuing goal, whereas the training of child and adolescent psychiatrists to meet the potential need is beyond the realm of possibility. In the interim, what can be done to provide a way to intervene for the promotion of child mental health? Obviously, one focus is on developing prevention programs in general health and education systems. Second, training primary care practitioners from numerous disciplines is needed to provide basic child mental health services. Basic assessment and treatment are possible, with triage of the most severely disturbed. In a WHO Atlas project focusing on the Eastern Mediterranean Region (166) it was noted that only 67% of countries surveyed had a system for providing inpatient mental health care for children and adolescents, only 53% of the reporting countries include information about child and adolescent mental health in their annual health reports and the majority of countries in the region lack national standards of car for child and adolescent mental health.

McKelvey et al. (167) illustrate the differing priorities for child psychiatric services in Vietnam, where there is a focus on infectious diseases and malnutrition. Treatment is reserved for the most severely afflicted, especially patients with epilepsy and intellectual disability. Specialized care is available in only a few urban

centers. In rural areas treatment is provided by allied health personnel, paraprofessionals, and community organizations.

In some countries, the lack of child mental health personnel has stimulated some remarkable efforts to train persons from diverse backgrounds to be effective in identifying and intervening to ameliorate child mental health problems. In Alexandria, Egypt, child counselors have been trained to develop sophisticated interventions in schools (168).

Program Illustration

In Alexandria, the Department of Community Medicine has supported the development of a cadre of school counselors. These counselors come from the ranks of volunteers, social workers, and psychologists. Without prior child mental health training, the workers are provided with coursework on common child mental health problems and then are supervised in field placements. The counselors work with parents around children identified by both the school and parents as having some type of behavioral problem. They also serve as contact points for the school, parents, or pediatricians to bring children with more severe behavioral disturbance to the attention of the few fully trained mental health professionals.

Leaders in child mental health programming in resource-poor countries are emphatic when faced with the reality of program implementation that Western models of care by specialists are neither feasible nor desirable. Indigenous methods and models of care need to be developed that are not dependent on specialists. Conversely, the development of these models that use parents, teachers, pediatricians, and others can be informed by the best thinking of child psychiatrists and other specialists. This has led to an emphasis on the training of primary care practitioners. Furthermore, short-term, focused training in specific areas related to diagnosis or intervention can be provided by specialists or through specialized child psychiatric centers that have a broad regional or national area of responsibility.

The development of child mental health training for primary care practitioners is well established in many sites, but the WHO Atlas documents and other studies document that the utilization of primary care providers falls far short of the goal in both developing and developed countries (164,169). Murthy (9) describes the use of primary health care providers in resource-poor countries. In India, with 1.5 billion people, there are only 5,000 mental health providers—of whom only a fraction are psychiatrists—35,000 psychiatric beds, and a dearth of emergency services. The primary care provider, when adequately trained, is a valuable and essential point of contact and treatment for the mentally ill. In India, it has been demonstrated that primary care providers can provide a level of professional care that reduces morbidity and mortality. However, without appropriate training, primary practitioners have been shown to have a poor record of recognizing mental disorders.

Giel et al. (169) report in their study in resource-poor countries that primary care practitioners identified only 10% to 20% of the disorders that the researchers were able to diagnose. WHO has devoted considerable efforts to the development and distribution of training manuals to aid primary care practitioners in the recognition of child mental disorders (170,171).

Moreover, India has developed the anganwadi system to provide basic nutrition and educational support in villages. This is both an appropriate preventive intervention and a way to assess youngsters presenting with disorders (172). The anganwadi system focuses on providing essential services to very young children. Like Head Start, the program provides nutrition, basic education, socialization, and a venue for more specialized intervention for children perceived to be at risk or in need of additional services (172). There must be a concern in the development of these indigenous systems of care that not too much dependence be placed on family structure and support at a time when urbanization and industrialization are eroding the traditional family structure. With the absence of security, and often living at a subsistence level, the new nuclear family faces previously unknown challenges and may be particularly vulnerable over this and the next generation.

Some programs are international in scope. For instance, WHO, as part of its Program on Mental Health, fostered the use of life skills education (173). The goal of the Life Skills Program is to foster psychosocial competence. For children and adolescents, the Life Skills Program is taught in schools. The program itself as promulgated by WHO is based on the social learning theory of Bandura (174). Many similar models are operative throughout the world. A "training the trainer" component affects the overall resource of a community to provide for the mental health needs of some children and adolescents who are at risk. The "training the trainer" model has now been critiqued in an effort to improve outcomes from such programs (175). Among the obvious limitations in the developing world are the absence of universal education and the capacities of the teachers to go beyond essential educational tasks. Kapur et al. (176) demonstrate that the training of teachers as counselors was effective in India.

The prospect for the future of child mental health practice in resource-poor countries is tied to economic growth, health literacy, and reduction of stigma. The creative efforts to develop programs to reach children and adolescents in resource-poor countries need to be supported. Child and adolescent psychiatry will remain a scarce resource to be used in ways that will have a duplicative impact. This means that the training of volunteers, the training of peers, the support of family intervention programming, and the use of community-based early intervention need to be the focus of attention. Kim (177) proposed a curriculum guideline of cultural competence for child and adolescent psychiatric residencies. These guidelines stress ethnogeneric and developmental perspectives, which can be expanded further to include ethnospecific issues depending on the needs of each training program.

The notion of a continuum of care as advocated as a goal in developed countries is but a fantasy in the developing world, where there remains a reliance on inpatient care for the most seriously disturbed, and where outpatient care is often sparse. In some developing countries the Western model of managed care and the institution of various insurance schemes are underway. Unfortunately, the negative consequences of these aspects of care systems are too often unrecognized. In some countries the introduction of insurance has had the unintended consequence of reducing access for uncovered populations and has led to flight of health professionals into the private sector.

RESEARCH

Ordóñez and Collins (178) call for advancing research to action in global child mental health. They point out that although 90% of the world's children live in developing countries, only 10% of randomized control trials testing mental health interventions for children. The grand challenges included the development of locally appropriate strategies to eliminate childhood abuse and enhance protection and to reduce the duration of illness by developing culturally sensitive interventions across settings. Cullins and Mian (179) adduce evidence for the integration of culture into meeting the global challenges in child and adolescent mental health. Techniques include task shifting and the incorporation of culture into evidence-based research and into its implementation.

Patel and Kim (180) reviewed original research contributions from LAMI countries published over a 3-year period in the six highest-impact general psychiatry journals and found that only 3.7% of published research comes from LAMI countries, which account for over 80% of the global population. The authors proposed several explanations for their findings including the low proportion of submissions from LAMI countries, the possibility that authors might be choosing local journals for their research, and the low research output and research capacity in these countries. In addition the authors suggested other potential explanations on why articles from LAMI countries are more likely to be rejected including the quality of the research and editorial and reviewers attitudes toward articles from these countries, a view shared by others (181).

Earls and Eisenberg (182) highlight three areas for enhanced research activity in relation to child and adolescent mental health. First is research to understand how the changes in contemporary society are reflected in the prevalence and incidence of mental disorders. Second is research to enhance the understanding of how different childrearing methods affect normal and deviant behavioral and emotional development. Third involves research on the design and delivery of mental health services. Mohler (183) describes and discusses the major challenges in cross-cultural research on child mental health. Nelson and Quintana (184) present

strategies for designing and conducting qualitative investigations, and address ethical issues involved in conducting qualitative research with minors. International child development and mental health studies often call for a mixed-methods approach (185).

Hamoda and Belfer (24) note that while the obstacles to collaboration internationally are understandable they can be overcome with careful planning, development of trusting relationships, and attention to seemingly mundane impediments, such as, language, financial transactions, International Review Board approvals, among others. Eisenbruch (186) has defined a template for the steps needed to ensure cultural competence in research, namely cultural competence in community engagement, communicating with research subjects, design, cross-cultural validation of research instruments, sampling, calibrating diversity variables, demographic variables measured in datasets, research ethics, data collection techniques, data processing and analysis, and dissemination and action. Culturally competent community engagement by the researcher, for example, depends on (a) building community partnerships; (b) developing interventions that are acceptable and relevant; (c) promoting successful recruitment, participation, and retention of participants; and (d) developing a diverse, cohesive, and committed research team and effective managerial information support systems. International child psychiatry research program should pay attention to participation from the perspective of community members (187). International child psychiatric research should avoid sampling barriers among culturally diverse communities to do, for example, with lack of tolerance of diverse groups, social stigma, concern for issues of confidentiality, and fear of exposure because of possible threats to security (188,189). The research should avoid the use of instruments developed in one culture transferred to another given the cultural differences in the interpretation of certain items. The research should avoid definition of diversity with only a single variable. Cultural, racial, religious, and immigrant groups are not homogeneous (190). For example, any one population includes native-born, migrant, and immigrant peoples with distinctive national origins and regional settlement patterns, and varied and complex demographic structures. Data collection should be clear about descriptions of ethnic or racial measurement and reasons for including or excluding clearly defined populations. The research should be open to innovative recipes for data collection, for example, as proposed by Roszak (191) with clarity about (1) who provides information; (2) when data are collected; (3) which racial and ethnic categories are used—all hospitals should use standard racial and ethnic categories; (4) how data are stored; and (5) responses to patients' concerns. Nikapota (1) underscores the importance of determining "culture-appropriate" criteria to permit consistency in diagnosis. In doing research, it is important to consider the characteristics of the interviewer as well as the informant.

Fontes (192), drawing on his experiences conducting research on sexual abuse in

a shantytown in Chile and with Puerto Ricans, examined ethical issues in cross-cultural research on family violence. It was emphasized that special attention needs to be given to informed consent, definition of the sample, composition of the research team, research methods, and potential harm and benefit. Munir and Earls (193) articulate a set of ethical parameters for research that must be considered in doing research among children and adolescents of resource-poor countries. To apply a different standard justified by the difficulty of implementing protocols would violate the very support of a rights framework so essential for progress to be made on behalf of children in resource-poor countries.

An area of great interest is the development of assessment tools that incorporate the diversity of cultural parameters. Increasing numbers of instruments have been translated and back-translated for use in cross-cultural studies. Instruments exist for the assessment of depression, anxiety, PTSD, quality of life, and other conditions. It remains for there to be a sufficient body of cross-cultural research with modern standards for the conduct of the research that yields information on the reliability and validity of the instruments in their revised versions. Few instruments meet an agreed standard for use across all cultures in their current form.

As described by Earls (194) compulsory schooling leads to the need to understand the impact of learning disorders better. The appropriate diagnosis and remediation of these disorders are first-order priorities in countries where technologic advance places a premium on knowledge acquisition and use. As yet, research in this area has not been implemented in resource-poor countries, but the pressure to implement such studies is mounting.

Research into the understanding of the differential impact of childrearing methods should be an area of collaborative inquiry between those interested in mental health and those concerned with the role of women and the family in evolving societies. It is not evident that any one method of childrearing is superior to another. Perhaps developing and developed societies can learn from one another about the optimal methods for childrearing in the presence of the evolution of individual societies. The experience with the effects of urbanization, industrialization, changing roles of women, and increased survivorship of children in developed countries may form the basis for translation into the programs for resource-poor countries. Conversely, the healthy development of youngsters growing up in adversity in resource-poor countries may provide information on how to enhance understanding and to develop new interventions for children at risk in developed countries.

Attention needs to be focused on the important developments in global and international child mental health that are published in peer reviewed journals in languages other than English. A mechanism is needed to ensure that these key findings are not lost to the English-speaking world (195).

PREVENTION

It appears that prevention of mental disorders is the way to approach the problem of reducing the toll of mental illness in resource-poor countries. Many of the mental health issues that need to be addressed are inextricably related to contextual issues, as noted earlier. One area too often overlooked in considering a way in which mental health problems can be prevented is through the overall reduction in malnutrition. The effect of malnutrition in societies impacts both the child directly and the parent who cares for the child. Both lead to significant mental health consequences that are preventable. The consequences from malnutrition can be delayed cognitive development, but also more subtle behavioral manifestations with attentional problems and learning disabilities (196,197). Some studies suggest that the behavior disorders associated with malnutrition are secondary to impaired maternal capacities and not to the malnutrition itself, because malnutrition does not appear to contribute to behavioral disturbance later in life although this remains an open question due to lack of a sufficient number of longitudinal studies (198,199). Thus, mental health professionals working in the international arena must be mindful of this issue and consider it in their assessment of mental functioning, as well as advocating for proper nutrition as a preventive measure (200). There is an opportunity to reduce some behavioral and cognitive problems through a reduction in malnutrition.

Maternal depression associated with malnutrition, poor health, social deprivation, abuse, or other stressors affects the child and adolescent as well as the mother. This too is a preventable cause of childhood mental disorder, as demonstrated by Beardslee et al. (201). Using a family-based approach, Beardslee and colleagues sought to reduce risk factors and enhance protective factors for early adolescents. They demonstrated that providing parents with information about their affective state, equipping them with enhanced communication skills, and fostering parent–child dialogue led to an improvement in children's self-understanding and children's depressive symptomatology. This program is now being replicated in Finland, Costa Rica, and elsewhere (202).

Life skills education promoted by the WHO is the backbone of prevention programming in many resource-poor countries (203). Life skills training is provided in the context of the school curriculum as a program to enhance psychosocial competencies. The training focuses on basic, generic skills such as decision-making and problem-solving, creative and critical thinking, communication and other interpersonal skills, self-awareness and empathic skills, and coping with stress and with emotions. The aims are to promote mental well-being and to enable children to take more responsibility for their lives and feel more effective (205).

The World Psychiatric Association Presidential Global Program for Child Mental Health identified school dropout as a major issue in both developing and developed countries. Intervention to prevent dropout was considered to be an important preventive strategy related to child mental health. The program conducted research

on school dropout and prepared materials for use by clinicians and educators (206). The Global Program has produced other materials to support preventive intervention in resource poor countries (206).

Schools have an important role to play in mental health promotion, prevention, and early identification of children in need of services. Programs that focus on social, emotional and academic learning from kindergarten through high school have been found to improve school attitudes, behavior, and academic performance (207). Social development, including meaningful peer relationships, can improve academic achievement and motivation, while negative peer pressure or social disapproval toward school work might lead some students to drop out (208). Not only is effective social and affective education of direct benefit to academic attainment, it also improves teacher effectiveness and satisfaction (209). These findings from a host of educational initiatives have been difficult to adopt in countries where the metric for success is often dependent on rote learning and performance on examinations.

SYSTEMIC ISSUES

Throughout the world, it is rare to see child mental health being incorporated into national health policy (210). This lack of policy was documented in 2005 (164) and in the ensuring decade relatively little progress has been made despite the recognition of the importance of policy for good governance and program development. In many countries, developed or developing, no coherent health policy exists that would provide a framework for program development. In countries with a health policy, child mental health rarely rises to a prominent position. Until child mental health becomes integrated into health policy, stable budgetary support for child and adolescent mental health programs will not be realized.

Advocacy for child and adolescent mental health is evident throughout the world, but competition with other interests often forces the issue off the policy agenda. Intersectoral competition and lack of collaboration is too often the limiting factor in developing the type of collaborative programming needed for children and adolescents with mental health problems. When crises involve children, such as child soldiers in the Sudan or female genital mutilation, the issue of child mental health, for a time, gains the spotlight. Unfortunately, the advocacy and concern diminish with time and rarely find a sustaining constituency.

Nongovernmental organizations play an important role in promoting child mental health, in disseminating information, in providing a forum for professional exchange, and in advocating for specific causes. The constituent base of these organizations differs, but they generally have broad representation and provide an opportunity for interested persons to learn more about specific topics or develop ideas in a context of knowledgeable individuals. Many of the nongovernmental organizations have affiliated regional organizations that permit ongoing local involvement. However,

from a policy perspective NGOs may allow governments to avoid their responsibility to support capacity building or to allow special interests or disorder specific initiatives to skew the development of rational care programs. National organizations have often taken leadership roles in advocacy efforts and crisis response. The following are some of the more established international nongovernmental organizations focused on child and adolescent mental health: the International Association for Child and Adolescent Psychiatry and Allied Professions, the World Association for Infant Mental Health, the International Association for Adolescent Psychiatry and Psychology, and the World Federation for Mental Health.

It is important for child mental health to be recognized in the various global initiatives seeking to reduce mortality, foster mother and child development, and otherwise to aid human development. The Millennium Development Goals promulgated by the United Nations highlighted important goals for reducing maternal mortality, and a host of other conditions. The framework provided a benchmark for countries. Mental health was not identified in these development goals, but improving mental health was important to reaching the goals in many areas. Recently the UN Sustainable Development Goals have been promulgated for the next decade (211). The Sustainable Development Goals for the first time identify mental health–related goals; however, again child mental health is not identified as a standalone area.

The lack of trained individuals in resource-poor countries and the maldistribution of professionals in developed countries is a significant impediment to the development of child and adolescent mental health services. The WHO mhGAP (212) program has for almost a decade provided a comprehensive set of guidelines for the closing the treatment gap, particularly in LAMI. mhGAP has emphasized the need for developing primary care provider competencies and for the implementation of task shifting. The guidance and associated training is now widely available. Child mental health is recognized in mhGAP but not as a primary focus.

The limitation for program implementation is the availability of trained persons as recognized in mhGAP for leadership and “training of the trainer.” However, it is increasingly recognized that the training must be more sophisticated in its implementation and more sustained that was initially thought. Bolton et al. identified the “apprenticeship model” for training and most recently suggested a “common elements treatment approach” (213). Both seek to ensure quality training that will be sustained. This can counter the too-facile adoption of interventions and strategies that do not fully appreciate local culture and the appropriate utilization of available resources. Further, there is the need for these programs to be able to access tertiary diagnostic and treatment services for those with manifest psychiatric disorder and in this regard new efforts at telepsychiatry and the use of mobile diagnostic devices hold promise. Efforts to support training are now ongoing through many nongovernmental and governmental efforts. The training of a sufficient number of

individuals to implement appropriate, accessible care will be an ongoing challenge.

LESSONS TO BE LEARNED

It would be wrong to focus only on the areas where it appears that more could be done to enhance child and adolescent mental health services. Western mental health professionals and program developers can learn from the programmatic necessities and innate capacities of individuals and families in resource-poor countries.

Family participation in the care of the mentally ill or retarded children in resource-poor countries is impressive by any standard. The acceptance by communities of the special needs of affected families is often dramatic. Likewise, the willingness and ability of families to care for children, including the appropriate use of medication, for children with epilepsy and other disorders challenge Western concepts of continuity of care and the role of providers.

While the West has flirted with the enhanced use of primary care providers in the delivery of mental health services, but in resource-poor countries, necessity has led to impressive models for the training of primary care practitioners, as noted earlier. Primary care training for specific mental health interventions is also part of a WHO mhGAP strategy (214).

Conversely, there is a global trend toward the imposition of managed care on mental health services. This is occurring in countries, such as China and Eastern Europe, which have hardly met their child and adolescent mental health needs. The need is felt to control the cost of mental health services. Perhaps uncritically, economies throughout the world are adopting managed mental health care. From a Western perspective, it is obvious that although all mental health services suffer in a managed-care environment, child and adolescent mental health services are often most vulnerable to reductions and the use of the lowest common denominator service. Research into managed care and health services has not had the beneficial impact of stimulating the development of innovative systems of care. Unfortunately the investment needed to foster these systems of care and the social network needed to provide “wraparound” services do not exist in resource-poor countries. It remains to be seen whether traditional systems of care can be integrated into a meaningful continuum.

EMERGING ISSUES

The impact of globalization and political change underpins much of this chapter. Globalization and modernization bring new challenges to the attention of child and adolescent mental health professionals. On the positive side for child mental health is growing support for a democratic process within the family, the public awareness

that children have a mental life and that they can suffer from depression and other disorders, a reduction in the stigma associated with seeking professional help, the passage of laws assuring basic children's rights, the many initiatives for capacity building in developing countries, reforms in education, and the enhanced training of mental health professionals in many countries. International adoption, the use of telepsychiatry in the developing and developed world, the role of industry and the for-profit sector in program development and education, and the increased recognition of the need to address the mental health consequences of conflict and natural disaster will be an ongoing challenge to professionals and those impacted by mental illness.

CONCLUSION

Global child and adolescent mental health is no longer an exotic topic for theoretical discussion. With our global village, knowledge of child and adolescent mental health problems throughout the world is an important part of the education of all child and adolescent psychiatrists and allied professionals. The perspective gained from appreciating the stressors of children and adolescents in parts of the world embroiled in conflict and the nature of the responses offers the opportunity to learn more about the resilience of children and adolescents and about what we must do to develop more effective intervention programs.

The dearth of trained child and adolescent psychiatrists and allied professionals in developing countries challenges us to find the most effective means for inculcating knowledge and providing meaningful services. It is unrealistic to assume that any effort will meet the needs of child and adolescent psychiatry as determined by conventional planning assumptions. As services evolve in developed countries, there is probably much that can be learned from the way in which less developed countries have found the means to support families and individual persons to be relatively self-sufficient even when they are affected by mental disorders.

Given the enormity of the challenge to extend child mental health in a meaningful manner globally there will be a need to adopt a more public health approach to addressing the mental health needs of children and adolescents (215). Likely, there will never be enough fully trained child and adolescent psychiatrists globally so finding the way to provide quality care through effective training will be a challenge. Recent movements toward task shifting and task sharing will need to be studied and the way in which more highly trained individuals can impact this trend will need to be monitored.

CHAPTER 1.6 ■ CHILD AND FAMILY POLICY: A ROLE FOR CHILD PSYCHIATRY AND ALLIED DISCIPLINES

WALTER S. GILLIAM, MATIA FINN-STEVENSON, LAINE TAYLOR, AND EDWARD F. ZIGLER

Child and adolescent psychiatrists and their allied discipline colleagues have long understood many of the family and societal factors that impact children's development and functioning (e.g., poverty, community violence, substance abuse, substandard education, family discord). Many of these contributors to psychiatric impairment have been the focus of public concern, debate, and often policy development. Although child and adolescent psychiatrists and other mental health professionals have much to contribute to thinking about population-wide efforts to address these problems, few receive any training on how to understand effective policy development or their role in it.

In this chapter, we discuss some of the social changes we experience in our society, their impact on children and families, and policy responses to address these. We also discuss the role of mental health professionals in the policy arena. As will become apparent in the course of this chapter, there are benefits as well as challenges inherent in the utilization of mental health research in policy settings. A number of opportunities exist for mental health professionals to contribute to the development of policies for children and families. However, their effectiveness is dependent not only on their scientific and clinical knowledge but also on their familiarity with the social policy process and their ability to work with policymakers.

WHAT IS POLICY?

Policy is any agreed-upon set of principles used to guide decisions or procedures. Policies often are codified in written forms, such as laws, governmental regulations, or organizational procedures. In many cases, however, policies are not explicated formally and exist simply as implicit assumptions about "the way things are done." In democratic societies, the most formal type of policy is legislation—the laws enacted by state and federal governments that create and fund service programs (e.g., health care, public-funded prevention services, entitlement services for persons with disabilities), establish or alter rules for government services (e.g., procedures for arbitrating disputes regarding special education), and regulate the way individuals and private businesses may interact (e.g., mental health parity laws regarding insurance providers, laws regarding domestic violence and protection). Regulations, as opposed to legislation, are governmental procedures and definitions that are

developed by executive branch staff to guide the provision of their services, but do not rise to the formalized level of legislation. What differentiates policies is the degree to which they have been formalized, who they regulate, the consequences that can be imposed for breaking them, and how difficult it is to change them. What all policies have in common is that in all cases someone first envisioned the need for a policy, someone decided what the policy should be, and some individuals actively or implicitly agreed to it. In many cases the persons writing and deciding policies understand the policy process very well, but may have little or no knowledge of the systems they are regulating or the implications of their policies.

Over recent decades, researchers and clinicians in psychiatry, developmental psychology, and other disciplines related to mental health, as well as professional organizations representing these professionals, have become increasingly involved in the shaping of policies and legislation designed to address the mental health challenges of children and youth. While the focus of legislative action on behalf of children is not new, the presence of researchers and clinicians in the debate has added a different dimension, offering new opportunities for interaction between research and policy.

The interest in social policy among mental health professionals was precipitated by a number of developments. One of these was the recognition that children develop within the social context; they are influenced by various aspects of their immediate environment as well as by the more remote social institutions such as the school, the workplace, government, and media (1). This led to policy responses and the development of programs to address the health and mental health needs of children. An example is the implementation during the 1960s and 1970s of federally sponsored social programs such as Project Head Start (2). The proliferation of such programs, and the funds made available for them, enabled researchers and clinicians to apply their knowledge and training to such areas as program development as well as become involved in and refine the understanding of policy and program evaluation (3). The integration of child development research and social policy has become so entwined in both the research and policy arenas that in order to secure funding for research, it has become necessary to demonstrate the practical application of findings and their potential to address unmet needs (4).

The problem of unmet psychiatric needs in children has been acknowledged for decades, as well as the contributory societal forces needed for proactive policy remedies (5). Between 10% and 20% of US children experience some form of diagnosable mental illness, and the aggregate cost of mental illness in terms of both direct and indirect costs to US taxpayers continues to climb (6). However, only a small proportion of the overall health budget is directed to children (7). Also, the recent health care reforms that have replaced fee-for-service care with managed care have had both a positive and negative impact on mental health care for children and adolescents. Although access to health services in general has increased for young

people (8), with the emphasis on brief, problem-oriented approaches, it has become more difficult for children with serious emotional disorders to obtain the level of needed care. Additionally, 90% of health care expenditures for children are consumed by the 15% of children who have chronic illness and disability, leaving little for mental health care for the vast majority of children who need it.

WHO SHAPES POLICY?

Within the world of health care, there are several types of individuals whose work are critical in shaping policy and helping to move proposed bills into law. There are even more individuals involved in assuring that those policies that require funding receive appropriations. Researchers and clinicians have an opportunity to inform the policy process through various activities, such as conducting policy-relevant research, providing expert testimony, and informing policymakers of social and economic trends that may contribute to child and adolescent health problems and require a policy response.

Policy Analysts

These are individuals who most commonly hold a masters degree, juris doctorate, or PhD and work for government or policy think tanks. A think tank is an organization who is endowed or funded to work on specific issues (i.e., health care, housing, and defense). Think tanks employ policy analysts to do research on these topics that are later used to inform policy (9). An example of a think tank that focuses much of its research on health care policy is the RAND Corporation. This corporation is primarily federally funded. The U.S. Department of Defense, branches of the U.S. military and the Department of Health and Human Services contribute the largest percentages of the organization's funding. RAND develops research to evaluate existing policies and identify policy gaps. Within organizations such as RAND, policy analysts are employed to review extant research and complete studies with the aim of scientifically informing policy (for our purposes, health policy specifically) that often directly impact policy language and funding of legislation (10). These individuals spend their days researching topics in health care, collecting and analyzing data, and publishing papers that help translate scientific results into policy language.

Lobbyists

A lobbyist is a person who works for an organization either for pay or pro bono to influence legislation directly. Lobbyists may work directly with legislators to influence language and initiation of bills or they may work to have constituents

contact legislators on specific raised bills. In addition to meeting with legislators, they also analyze, research, and educate others about issues pertinent to the raised legislation. Lobbyists have no specific educational requirements, but most have at least a bachelor's degree and have completed internships with lobbying groups or in government (11). While there are no educational requirements, there are laws that regulate the activities of lobbyists, amount of time an organization can lobby, and the amount of money that can be spent on lobbying activities. Lobbyists must be registered with state and federal governments. This registration monitors the activities of the lobbyist and for whom they work. California requires lobbyists to participate in an ethics course.

Advocates

The terms *advocate* and *lobbyist* are often used interchangeably. However, there is a distinction between the two. As we have covered, lobbyists work to directly influence specific legislation. An advocate is an individual who supports or promotes dissemination of information on a particular topic or issue. Advocates work to promote awareness about issues through direct discussion with law makers, supporting activities, educating the public, and creating networks of influence. Both advocates and lobbyists have relationships with legislators and influence policy, but advocates often focus on an issue, while lobbyists often focuses mostly on a specific piece of legislation. There is no specific education or registration for policy advocates (11).

Policy Consultants

A public policy consultant serves to inform the public and the organization on a particular issue. They may inform a community on issues of child mental health through partnerships with community organizations, developing outreach programs, or working with various media outlets. They inform the organization about policy relevant to the organization and research the impact that the organization has on their community. A policy consultant usually has a master's degree in a policy-related field. The consultant influences policy through the organization's influence in their community and through relationships with policy makers (11).

CONTRIBUTORY FACTORS AMENABLE TO POLICY IMPACT

Many social and environmental risk factors are implicated in the onset of mental dysfunction. Included among these risk factors are prolonged separations between the

parent and child, physical or sexual abuse, poverty, marital discord, parental psychopathology, instability in the family environment, and a variety of other stressors related to family life. Children who experience one of these risk factors may not be any more likely to suffer serious consequences than children with no risk factors (12). However, the more risks or stressors that are present in children's lives, the greater the probability of damaging outcomes. Also, some risk factors compound other problems. For example, low birth weight and central nervous system difficulties in isolation often may have no discernable negative effects, but may be exacerbated if the child is raised in an unstable, low-income, or stressful or unresponsive family environment (13).

Access to Health Care

The Affordable Care Act (ACA) was comprehensive health care legislation passed in 2010 that aimed to increase access and affordability of health care for all US citizens. Its comprehensive nature precludes many from understanding how it pertains to them as an individual health care consumer or practitioner. Therefore, we will cover aspects of the ACA that are particularly pertinent to the practicing child and adolescent psychiatrist.

The first area to discuss is the expansion of coverage. This is important for child and adolescent psychiatrists as many more children seeking mental health care will have private insurance. The number of individuals with insurance overall has increased and the reinforcing mental health parity act means that more children will also have mental health coverage (14). Prior to this law, many children were not covered by any insurance (including Medicaid) leaving the costs of treatment in the hands of parents or hospitals in the form of indigent care provisions.

In order to enforce this coverage expansion, the federal government established incentives and penalties. One incentive for states is that they will get federal support for Medicaid programs to start mandatory health care exchanges. An exchange is an online health insurance marketplace where consumers can compare various policies and be informed about their individual incentive-tax credits. The government provides for graduated tax credits for individual incomes at 100% to 400% of the federal poverty level (15). The programs receiving federal support include Medicaid and the Children's Health Insurance Program (CHIP). Medicaid coverage was expanded to individuals at or below 133% of the federal poverty level (this was $24,300 for a family of four in 2016). CHIP is a program created by the balanced budget act of 1997. CHIP expands health coverage for children through a federal fund match for state Medicaid and increases the wage limit for children to access Medicaid insurance (16). If individuals and families are not insured through their employer or the exchanges, with some exceptions, then there is a tax penalty ranging from $695 to $2,085 and based on household income.

In addition to an increase in the numbers of individuals with increased access to health insurance, individuals saw differences in the ways that they were able to use their insurance and what their insurance covered. Firstly, insurance companies now have to report the percentage of collected premiums used on clinical services. If this is under 85%, then the insurance company is required to provide a rebate to their customers. Second, there may no longer be lifetime or annual limits on insurance use and an individual may not be excluded from being insured based on a pre-existing condition (17). The importance of this is that those with mental health disorders were hit hardest by these limits. For example, some insurance companies may stipulate only 30 days of inpatient psychiatric treatment per year. This would not impact some, but those with chronic and treatment resistant illness would reach a period in which their insurance would not pay, regardless of need. Thirdly, there are limits on the deductible that may be charged by the insurance company. This is $2,000 for an individual and $4,000 for a family. Also, insurance companies now must cover certain preventative health interventions. Finally, the Centers for Medicaid and Medicare Services may receive a 17.1% reduction in costs from pharmaceutical companies for medications exclusively developed for pediatric populations (17).

There were three important provisions of the ACA impacting children and pediatric providers that are not insurance related. One is that it reinforced the Mental Health Parity Addiction Equity Act of 2008. This law stated that mental health and addiction services must have equal coverage and reimbursement to medical services of a similar level. This landmark legislation is not yet fully enacted in many states as it is the responsibility of the state to ensure that this is occurring (18). The second provision is for an increase in funding to community- and school-based health centers. Finally, there was an expansion of funding for the National Health Service Corps (NHSC) to increase the recruitment of primary care practitioners (17). House bill 2646 seeks to have child psychiatrists included amongst the NHSC practitioners, and this bill currently is making its way through the legislation process at the time that this chapter was written.

Poverty

Numerous programs designed to mitigate the negative outcomes associated with poverty have been implemented over the years. Nevertheless, poverty's impact on children remains a grave concern. One in five children ages 18 and under live in poverty (19). Several contributing factors, such as single-parent families are noted. Other historically contributing factors are related to ebbs and flows in the economy, leading to cuts in public assistance and the decline in the real value of family income (20). The ramifications of living in poverty are numerous and include assaults on children's physical and mental health (21), brought on by unsteady access to health care, a lack of money to spend on health-promoting activities, poor nutrition, lack of

transportation, and inadequate housing (22). As a result, children in poverty have a higher mortality rate and experience greater health and mental health challenges (23), with the major pathways occurring indirectly through environmental stresses and feelings of powerlessness and frustration that often accompany poverty (24). The economy's impact on all families, not only those in poverty, can be significant. For example, the Great Recession of 2008 left many without jobs, and while its repercussions on individuals and families are still unfolding (25), impacts have contributed to an increase in child maltreatment cases (26).

The United States provides far less public income assistance to poor and single-parent families than many other industrialized nations. Instead, welfare reform initiatives, particularly those of the late 1990s, emphasize labor force participation as the route out of poverty. More recently, increases in the minimum wage have occurred, but wage rates remain low, particularly for less-skilled workers, and contribute to poverty. For two-parent families, low wages have been partly offset by the entry of increasing numbers of women into the labor force, but for single-parent families the escape from poverty is more difficult. The decline in real income affects adults and children. However, for children the consequences are particularly serious because a significant percentage of families in poverty are those with young children.

Sometimes new policies and legislation create new challenges. The most dramatic piece of US legislation for low-income children and families during the past 40 years was the Personal Responsibility and Work Opportunity Reconciliation Act of 1996, which included provisions for job training. This resulted in a 40% of reduction in the numbers of dependent families, along with a substantial increase in labor force participation by mothers (17). However, a primary implication of increased employment, particularly for mothers, was the need for child care. Many parents lack access to high-quality care for their children, either through availability or cost. A second implication of the welfare reform emphasis on employment was that some parents who have difficulty maintaining employment, often those with mental illness or substance abuse problems, were rendered ineligible for financial assistance, thus increasing the poverty of their family. Thirdly, welfare and immigration legislation has reduced access to noncash services such as Medicaid and food-assistance programs, affecting 20% of US children, increasing the effective child poverty rate (27).

Community and Domestic Violence

Although exact numbers are hard to quantify, there is little doubt that a large number of children are exposed to violence in their homes, schools, and communities as victims, observers, or perpetrators. Violence in schools received much media attention during the past decade, but despite several tragic incidents, has actually been declining (28), due in part to the provision of federal and state funding for after-

school programs which provide supervised recreational and educational activities for children and youth during times when school is out (29).

However, increasing numbers of children and youth are exposed to violence in other settings. In 2014, more than two thirds of children ages 17 and younger were exposed to violence within the past year, or at some time during their lives, either as victims or witnesses and were more likely than adults to be exposed to violence and crime (30). Such findings are troubling not only because of the threat to children's safety, but because of the short- and long-term impact on their healthy development (31). A key protective factor is a relationship with a caring, responsible adult, usually a parent (32). However, in some instances, parents may be emotionally or practically unavailable to their children, because they themselves may be the victims or perpetrators of violence. Therefore, the resources of other adults in the community need to be tapped, creating a great potential for community partnerships and school-based programs to lead the way in reducing violence among young people and to promote resilience.

Unfortunately, many children also experience violence in their own homes. While the issue of domestic violence has been on the policy and research agenda for several decades, the impact on children has received less attention. Such violence cuts across social strata, but is more prevalent among families living in poverty and is associated with multiple stressors, including substance abuse; in 30% to 60% of families experiencing domestic violence, child maltreatment is also present (33). Possible consequences for these children include behavioral and academic problems and depression, and in adulthood they may develop low self-esteem, and resort to violence and criminal behavior (34). Innovative approaches to address the needs of children involved in violence have been developed. One example of these is a collaboration among police departments and mental health professionals to identify children experiencing violence as well as provide needed clinical services and follow-up home visits (35). Another example is the use of canine-assisted therapy in schools to help calm the children and enhance their self-esteem and ability to cope (36).

Divorce

Divorce has become the norm for the majority of families. Although the divorce rate has peaked, most US children experience the remarriage of one or both of their parents or live in reconstituted families (37). While divorce is not necessarily insurmountable for children, stresses arising from the disruption and subsequent remarriage of parents can lead to psychological difficulties among children (38). The long-term effects of divorce and remarriage are related to a number of factors, including the child's developmental status, gender, and temperament; the quality of the home environment; mental health status of the parents; and availability of support

systems both to the parents and the child (39). Particular concern is noted for children whose custodial parent experiences extreme economic difficulties for an extended period of time and/or whose noncustodial parent fails to pay for child support (40). At substantial risk are children who are involved in prolonged custody fights. Many judges and lawyers are ill-prepared for the arduous task of determining the best interests of the child, not trained to consider children's needs and concerns or weigh the urgency of their condition and circumstances (41). Today, all states have statutes requiring that in all child custody cases, as well as in proceedings for termination of parental rights, decisions be made on the basis of the best interests of the child (42). Since such determination is often difficult to make, the courts often seek guidance from mental health professions (43).

Knowledge about how divorce affects children and parents should be disseminated not only among policymakers and those in the legal profession but also among other professionals who work with children, such as teachers. One important policy development has been the use of mediation services in divorce cases. These services are staffed by mental health professionals who have access to legal advice. Although initially begun as a way to curtail the high costs of divorce, families who have used mediation services note that one of the major benefits of the services is the availability of psychological support (44). Several successful support programs for children of divorce have been developed in schools across the United States (45). However, they are few in number and meet the needs of only a small percentage of the children who stand to benefit from such programs (46). Given the number of children who need such support, these programs should be made available in all schools, or at least in some schools in every community. The federal government can take a leadership role by making available funds that would finance the development of such programs.

Child Care, Work-Life Balance, and Family Leave Policy

Although numerous societal changes and potential problems are associated with women's participation in the labor force, none are as significant as the unprecedented demand for child care services. Today, the need for high quality, affordable child care is one of the most widely recognized social issue and has been a major problem for several decades. At the 1970 White House Conference on Children, the need for child care services was noted as the number one priority for the nation to address. However, two obstacles—ideological arguments against the use of child care, as well as the lack of public awareness of the need for child care services—stood in the way of policy action on the issue (47). As a result, the problem worsened, reaching crisis proportions as more mothers, especially those with infants and young children, joined the labor force.

There are numerous facets to the child care problem, one of these being the high

cost of services. From a policy perspective, the high cost of care is significant for at least two other reasons. First, child care costs are a major expenditure for families, and the amount of money families spend on child care is directly related to their income (48). Low-income families spend less on child care in absolute terms than do higher income families, but the proportion of the family budget that is taken up by child care costs is greater among low-income families, who have to allocate as much as 27% of their earnings to child care (49). Even for middle-income families, the burden of child care costs is great, as they do not qualify for state subsidies and pay higher taxes on their earnings (50). Second, there is a relationship between the cost and quality of care, with good-quality care costing substantially more than poor quality, custodial care. This being the case, there are inequalities in the quality of child care children experience depending on their family's income. The fact that good-quality care is a privilege that only some children are enjoying is of concern, because child care is an environment where children spend a large portion of every day and has significant effects on children's development and well-being (51).

The high cost of child care and lack of good quality care is an issue not only due to the possible harm to children, but also because it is a source of stress for parents. This has prompted discussions of the need to make changes in the workplace to create conditions that are supportive of family life, such as corporate support of child care services. Also, some corporations implement flexible schedules to allow employees time for child-rearing responsibilities (52).

Related to flexible work schedules is the need for family leave policies that would enable parents to spend time with their infants during the first several months after birth. The first few months of life represent a critical period for the development of attachment between parents and the infant, and within the context of a secure parent–infant relationship babies thrive and become increasingly autonomous (53). The first few months of life also represent a very stressful period that necessitate the adjustment of all family members to the newborn (54). Although the importance of such leave has been noted on the basis of medical and social science research for over three decades (55), adequate parental leave is still not available to most US parents. The Family and Medical Leave Act (FMLA) was enacted in 1993, granting 12 weeks of unpaid leave in any 12-month period to employees in companies of 50 or more workers. Its impact was limited by prior state legislation and exemptions for many employers (56,57). Furthermore, the leave was unpaid, and research shows that many have been discouraged from taking leave for financial reasons (58).

EFFECTING POLICY CHANGE

In order to effect positive policy change on behalf of children and families, it is important to note both the promise and problems inherent in research-informed policy

decisions, as well as the need for a cadre of professionals well trained to work at the intersect of clinical knowledge, research, and policy development.

Promise and Problems in Research-Informed Policy Decisions

There are numerous contributions that mental health professionals have made. For example, school-based programs have been developed by psychiatrists such as James Comer in an effort to prevent affective disorders in children and ensure responsivity to children's mental health needs. The authors of this chapter have also developed a school-based early care and family support program, known as the School of the 21st Century (21C). The program has been implemented in over 1,300 schools across the country (59) and has paved the way for a range of other programs that utilize the school building to provide academic as well as nonacademic support services for both children and families. 21C also inspired a renewed focus on the community school and the importance of addressing the needs of the whole child—focusing on all developmental pathways, including cognitive, social, emotional, and physical development. This point was noted by the National Institute of Health and is reflected in the 2015 Reauthorization of the Elementary and Secondary Education Act. This legislation, recently reauthorized as the Every Child Succeeds Act (ESSA), opens the door to assessing the school's climate and providing mental health and other support services.

Indeed, as a result of their involvement in program development and evaluation, mental health researchers have accumulated a vast amount of knowledge that "totally transforms the nation's capacity to improve outcomes for vulnerable children" (60). This knowledge, derived from over three decades of program development and evaluation, includes evidence of the effectiveness of a number of programs that reduce the burdens of risk factors in childhood, thereby reducing the probability of later damage (61). Fortunately, it is not necessary to change everything—the structure of opportunity, the neighborhood environment, and other aspects of the child's life—in order to make a crucial difference for children at risk.

The failure to utilize research to impact policy stems from several problems. One such problem is that the information on effective programs is generally not shared with the public or with policymakers (62). Even in cases where programs' potential benefits are known, there is skepticism that such programs, once they are replicated, will continue to be effective. Although this is a valid concern, successful programs can be built upon if we can attract and train enough skilled and motivated individuals, if we devise a variety of replication strategies, and if we resist the lure of replication through dilution. In efforts to serve as many children as possible or due to lack of sufficient funds, programs often are diluted, thus diminishing their quality and potential benefits (63).

Although an increasing number of mental health researchers are working in the policy arena, there is still a rather uneasy relationship between them and policymakers. Policymakers often regard researchers as impractical (64). From their perspective, they may be skeptical of policy recommendations coming from researchers who do not seem to understand the complexities of achieving a consensus among rival constituencies. Researchers, on the other hand, seem to regard policymakers as disingenuous and too willing to compromise even when the research evidence does not justify such action. Part of the tension and mistrust between policymakers and mental health researchers emanates from the assumption that knowledge from research is value free, whereas policies are made in a complex value-laden context (65). However, this characterization of research and policy is misleading. Often, scientific research takes on the values of the investigators, as is evident in the questions asked, methodologies employed, and the interpretation and presentation of the findings.

Problems such as these impede the utilization of research in policy settings. The problems are further exacerbated by the fact that researchers are often perceived as unable to provide clear answers to policy questions, or, looked at from another perspective, that policymakers are unable to ask questions in a way that would lead to valid and reliable research. In part, this problem stems from the unrealistic expectations among policymakers and the inability of many of them to appreciate that single studies cannot, in and of themselves, provide definitive answers to questions. But researchers also contribute to the problem. Often researchers are unfamiliar with the policy process or are unable to "read" political issues. They hold to long, slow standards of proof and refutation that are, in the policy arena, "obstructive and nihilistic" (66). Although it is imperative that researchers uphold their professional standards and credibility as scientists (67), there are times when findings from the research, even if they are not entirely conclusive, can nonetheless provide a direction for policy. For example, the research on the effects of child care on children's development was controversial, yielding conflicting findings that served to confuse the public and policymakers (68). Although research on the topic continues, researchers were able to convene and come to a consensus that indicated that as long as young children are in a good-quality child care settings, they will not be adversely affected by their experiences in child care. This led to a policy recommendation for efforts to monitor the quality of care children receive and ensure that all children receive care that is conducive to optimal development (69). It is apparent that there are circumstances, such as the increasing number of children in child care, when awaiting definitive conclusions from the research is counterproductive, especially when action can be taken at the same time that research on a particular issue is continuing.

A different problem occurs when research findings are misused by academics or the media to support a vested policy interest. An example is the controversial issue

of the importance of the early years in child development. The findings on brain research have been illuminating, although in many cases preliminary, and have shown the developmental importance of the first three years of life. Such studies have captured media and policy attention. Some researchers, excited by the window of opportunity for action on behalf of children, made exaggerated and distorted claims not substantiated by the research (70). The debate has been taken up by the national media, with viewpoints expressed through sound bites, undermining the complex scientific findings of decades of research (71).

Training the Next Generation of Policy Shapers

Understanding what impedes the use of research in policy is important if mental health researchers are to have an impact in the policy arena. To encourage the use of research in carving out policy directions, researchers should (a) be concerned in a nonpartisan way with the values and interests of society in general and children in particular, (b) take a practical approach and suggest policies that are feasible and have a chance of attracting widespread political and public support, (c) respond to the needs of policymakers and provide them with recommendations for action on the basis of research findings, and (d) become cognizant of and responsive to the policy process (72). Researchers also should make serious attempts to disseminate their findings to the greater world outside of academia, not only to policymakers but also to the general public. No society acts until it has a sense of the immediacy of the problem (73). Unfortunately, many professionals who understand the needs of children and families best have little or no training or experience in the media and policy arenas.

Fortunately, child and adolescent psychiatrists, developmental psychologists, and other mental health professionals are becoming aware of the need for public education on the needs of children (74). And, in a departure from their past practices, many mental health professionals are no longer satisfied with simply sharing information with one another. Rather, they disseminate their knowledge not only by presenting their findings directly to policymakers but also by taking steps to ensure that the information is covered in the popular media. Indeed, the dissemination of research in the context of the popular media has come to be accepted as an important aspect of the training received by some, yet still far too few, professionals in the field of mental health.

Some mental health professionals are also receiving training in the integration of child development research and social policy, learning not only about the policy process but also about some of the ways to merge their knowledge with that of policymakers in the formation of programs and policies for children. For example, in 1978 with support from the Bush Foundation in Minnesota, four university-based child development and social policy training centers were established, one of which

is the Edward Zigler Center in Child Development and Social Policy at Yale University. The Zigler Center has prepared doctoral students and postdoctoral fellows in a variety of disciplines related to mental health to apply their knowledge in the policy arena. Many graduates of the Zigler Center have gone on to work in the policy arena or in other universities where they have established courses and programs on the integration of child development research and social policy. The success of the training centers is evident not only in the increased number of researchers who apply their work to the policy arena, but also in the numerous issues, such as child care, parental leave, and the need for family support services, that only a few years ago were not discussed but that now command national attention. The success of these efforts is further evident in that an increasing number of policymakers are now acknowledging the importance of research in the formulation of policies and are actively seeking the collaboration of professionals in the field of mental health. If mental health professionals and policymakers continue to work together in this spirit of collaboration, we will be able to bring about much-needed changes that will assist family life.

CHAPTER 1.7 ■ MONEY MATTERS: FUNDING CARE

MARTIN KNAPP, DAVID MCDAID, AND EMMA WILSON

INTRODUCTION

The primary concerns of anyone working with children and adolescents with mental health issues are alleviation of symptoms, promotion of quality of life, support for families, and improvement of broad life chances. These should also be the primary concerns of anyone with responsibility for resource allocation, whether it is deciding how much funding can be made available, how it is shared between competing uses, or how to improve efficiency in its use. These latter concerns can be seen as economic questions, but they cannot be answered without a clear understanding of child and family needs and preferences, and the expected outcomes of interventions.

Interventions for children and adolescents include primary prevention of behavioral and emotional problems, services that respond to the emergence of such problems, treatments that directly address symptoms and their immediate consequences, and actions targeted on longer-term, broader implications for individuals and communities. For almost any such intervention to be successful—indeed, for it to be initiated—skilled staff are needed, supported by appropriate capital and other resources. Underpinning this process should be meaningful input from children and adolescents during the design, development, delivery, and evaluation of any intervention. In turn, because little in life is free, this requires commitment of the necessary finances.

The purpose of this chapter is to explore the links just outlined between finances, resources, and achievements. We first introduce a conceptual framework that summarizes the main connections linking resources to outcomes. One source of complexity that runs throughout the arguments in this chapter is that many children and adolescents have multiple needs, often prompting multiple responses—from health care, education, social work, criminal justice, and other services. Each service sector has its own funding streams and associated arrangements for allocating resources; we consider this mixed economy in the third section and the importance of integrated services, including both mental and physical. We then turn to a discussion of financing arrangements: How are child and adolescent mental health services funded? In judging whether financing arrangements are delivering the services and outcomes needed and wanted, we refer to two widely discussed performance criteria: efficiency (the balance between outcomes and what it costs to achieve them) and equity (whether outcomes, access, and burdens are fairly distributed). Achieving better performance by those criteria is often hampered. We therefore next discuss the resource barriers in the way of progress and the opportunities moving forward. The

concluding section summarizes the key messages.

THE PRODUCTION OF WELFARE

As a starting point, it is helpful to explicate the links between budgets, staff, and other resources hired or purchased, treatments and other services thereby delivered, and health and quality of life improvements hopefully experienced by children, families, and communities. A simple representation of a treatment and care system helps to identify the probable connections between key entities (Figure 1.7.1):

- *Revenue collection* is the process by which health, education, social care, and other systems receive money from individuals, households, employers, and other organizations. The funds thereby available to those systems are the purchasing budgets, to be allocated between competing needs and demands.
- *Commissioning* is the process by which purchasers (e.g., insurance funds and government departments) transfer funds to service providers in return for (usually) contractually agreed services.
- *Provider budgets* are the funds available to the bodies that actually deliver services, such as the operating budget of a hospital or citywide community program.
- For those services to be delivered (whether administering referrals, assessment, treatment, or supervision), *resource inputs* are employed: staff, buildings, equipment, medications, and other consumables.
- Some resources are not bought and sold in markets, such as family care, volunteer inputs (such as befriending or peer-mentoring), and support from faith and community groups. But these inputs are not really “free”: using them in one activity (in supporting children with behavioral problems, say) means they are unavailable for other uses (such as a volunteer or parent getting a paid job). In other words, there are *opportunity costs*.
- Services produced from combinations of the resource inputs can be labeled *intermediate outputs*. They indicate success: deploying funds to hire staff to deliver services is an achievement in its own right. But they are not the ultimate goals of mental health systems (which are usually expressed in terms of health and quality of life improvement). Relevant questions about these intermediate outputs concern volume (How many patients attend their appointments? How many therapy sessions are delivered? How many children are supported in a school-based program?), quality of care, and the characteristics of service users (“case-mix” in health care parlance).
- *Final outcomes* are the focal point of the whole system: symptom alleviation, fewer behavioral problems, improved functioning, educational attainment, and quality of life enhancement. Potentially, there are also outcomes for communities. Some final outcomes take years to reveal themselves fully. Few can be assessed adequately without asking the individuals themselves about

their experiences.

- In between services (intermediate outputs) and outcomes are a number of mediating factors, such as the care-setting social milieu, young people's care histories, individual and family resilience, and staff attitudes. Although potentially very influential in determining the success of an intervention, they do not have a readily identified cost (since they are not usually marketed) and so they might get overlooked when attention focuses on how services are financed and what they achieve. These can be called *nonresource inputs*.

Revenue collection
• General taxation
• Private insurance
• Social insurance
• Out-of-pocket

Purchasing budget
• Health care budgets

Other agency budgets
• Social care
• Education
• Criminal justice

Opportunity Costs

Commissioning

Providing budget

Resource inputs
• Staff
• Buildings and other capital
• Medications
• Consumables

Intermediate outputs
• Service volume
• Quality of care
• 'Casemix'

Non-resource inputs
• Social environment
• User histories
• Resilience
• Staff attitudes, etc.

Final outcomes
• Change in user health status, quality of life, etc.
• Family and carer effects
• Societal consequences

FIGURE 1.7.1. The production of welfare framework, revenue collection, and commissioning.

This representation was originally called the production of welfare framework (1) and developed to underpin discussion of the economics of care systems because (loose) analogies could be drawn between production processes as studied in mainstream economics and treatment and support approaches found in health, social care, and education to improve individual and family well-being. The stylized framework in Figure 1.7.1 has the signal virtues of highlighting the core connections between what goes into this system (finances, resource inputs thereby purchased, and unfunded contributions of family members and volunteers) and what comes out (services delivered, and improved outcomes for children, adolescents, and families). Although it looks highly simplified to anyone familiar with psychiatric, education, social care, or justice systems, in fact this representation is more complicated than often assumed by strategic decision makers looking for "quick fixes." Pumping more money into a system will only generate better outcomes for children, adolescents, and families if all the necessary links are in place and are functioning properly. Thus,

revenue generation or collection needs to be planned carefully to avoid creating perverse incentives (see below), and skilled staff need support from other resources if they are to deliver quality services. Equally, organization of those services and the therapeutic approaches they employ should be chosen carefully to maximize the chances of successful resolution. This means looking not only at whether there is evidence of therapeutic effectiveness but also at cost-effectiveness.

Succinctly expressed, the success of a child and adolescent mental health system in improving health and quality of life will depend on the mix, volume, and deployment of resource inputs and the services they deliver, which in turn are dependent on available finances.

A MIXED ECONOMY

Child and adolescent mental health services as narrowly defined and conventionally viewed sit in a complex, multiservice, multibudget world. This is because children and adolescents with behavioral or emotional problems and their families often have multiple needs. In well-developed, well-resourced systems, these needs could be identified, assessed, and addressed by a number of different agencies (including pediatrics, child psychiatry, education, social work, and youth justice), and could have wide-ranging impacts.

For example, in the United States Costello et al., using survey data, documented if and what type of services were used by adolescents diagnosed with psychiatric disorders in a 1-year period. Of the 45% of adolescents who received any treatment, most were likely to receive care in an educational setting (23.6%) or specialty mental health services (22.8%), with just 10.1% supported by primary care services (2). Glied and Evans Cuellar (3) describe how 92% of children with serious emotional disturbances in another US study received services from more than two systems, and 19% from more than four. In England, around 50% of looked-after children (i.e., formally in the social care system managed by municipalities) were reported having emotional and mental health problems that would likely require inputs from the health care sector (4). Snell et al. (5) found that the education system bears by far the largest share (89%) of the costs of services used by children aged 5 to 15 with psychiatric disorders in Britain (compared to 7% for the health system, and 4% for social care). In contrast, in France inpatient and outpatient hospital services remain the mainstay of child and adolescent mental health services (6). Survey data in Australia indicated that 49% of adolescents with mental disorders made use of school-based services in the previous 12 months; 42% and 21% had visited a primary care doctor or psychiatrist at least once, but only 6% had made use of hospital and specialist mental health services (7). A study of the impact of youth mental illness on the United States economy showed how a range of services contributed substantially to the $247 billion estimate, alongside costs associated with

lost productivity in employment and crime (8).

Multiple Provider Sectors

The resources described in Figure 1.7.1 might therefore come from any number of different systems. These services could be delivered by government (public sector), for-profit, or nonprofit organizations. Indeed, most countries have a thriving mixed economy of provision. There are additionally the multifarious contributions of parents, other family caregivers, and volunteers. Even health promotion strategies, which tend to be coordinated by public bodies, still need inputs from others, such as local communities (linked to the social capital effect).

Do these provider distinctions matter? Entities with different legal forms often behave differently in response to different incentives, and might be motivated by different goals. For instance, a government hospital may have different objectives and constraints from a for-profit hospital or a charitable hospital linked to a faith community. A school that provides emotional and behavioral health services may be focused primarily on pedagogical issues such as educational attachment or risk of classroom disruption by children with mental health difficulties. This may affect their modus operandi, patterns of resource dependency, and styles of governance. Distinctive motivations could influence how they respond to changes in funding levels and routes, market prices for staff or medications, competition or curriculum/time pressures on school teaching staff, with implications for costs, case-mix, quality of care, and outcomes (9).

Multiple Funding Sources

Another reason for distinguishing between provider types and the sectors in which they are located is because they are likely to have different funding bases. A treatment facility in the public sector—where most are located in the United Kingdom, for example—is likely to be heavily reliant on tax revenues or mandatory heavily regulated health insurance premiums, whereas a for-profit provider will probably receive more of its funding from private insurance plans or user fees. School-based behavioral health and social work services in some countries may be funded through the general education budget, which itself is usually funded through some form of taxation and whose use may even be at the discretion of the school principal. Services run by nonprofit and faith organizations might be funded under contract from government and by insurance payments, but could also receive charitable donations. Family caregivers, although ostensibly unpaid, might actually receive social security support or disability allowances tied to children's needs. Matching the diversity in provision, therefore, is a mixed economy of funding.

Interconnections: Transaction Types

Cross-classifying the main funding and provider types generates a large number of possible interconnections (Figure 1.7.2). This matrix describes just the broadest categorization of provider sectors and funding sources, but immediately demonstrates that the mixed economy of child mental health care is a highly pluralist system. Moreover, each combination of funding arrangement and provider sector could apply to the health, education, social care, criminal justice, and other systems.

There are many transaction types reflected in the links captured by this matrix. For example, tax revenues that support for-profit providers could be linked through performance-related contracts, tax breaks, or lump-sum cash subsidies. Payments from insurance companies to providers could be made through fee-for-service (FFS), capitation, or other mechanisms. Each transaction type will therefore have accompanying needs for regulatory frameworks for quality, probity, and perhaps efficiency in resource use.

Charting the broad contours of the mixed economy in this way helps identify the range and volume of services potentially available to children, adolescents, and families, and the means by which they are funded. It also emphasizes the inherent financial interdependence of different services and agencies. When the “expanded school mental health framework” initiated by the US government in the early 2000s encouraged education services to liaise with community mental health centers, health departments, hospitals, and others to broaden mental health promotion and intervention, implementation was hampered by “patchy and tenuous” (10) funding. In England, a taskforce set up to look at how to protect and promote child mental health put an emphasis on collaboration and joint working between health service commissioners, local government, children and young people, their families and schools (11), including training programs to support lead contacts in schools. It is up to schools to decide on the extent to which they will fund and provide most school-based mental health services, including counselling (12).

Revenue collection (funding)	Mode or sector of provision			
	Public/government sector	Non-profit/NGO sector	For-profit sector	Informal sector
Tax-based				
Mandatory health insurance				
Voluntary health insurance				
Charitable donations				
Foreign aid				
Out-of-pocket payments				
No monetary exchange				

FIGURE 1.7.2. The mixed economy. (Adapted from Knapp M: *The Economics of Social Care*. London, Macmillan, 1984.)

Coordination

Good interagency coordination increases the likelihood that individual and family needs will be met, which in turn might require collaborative approaches to financing to avoid yawning gaps in the spectrum of support. Even in well-resourced care systems there are large numbers of young people whose needs go unrecognized or undertreated, as we have already noted. This has also been highlighted by an independent Mental Health Taskforce in England, which recommended to NHS England that 70,000 more children and young people have access to high-quality support by 2020/21 by placing greater emphasis on prevention and early identification (13). Wasteful duplication of effort is another possibility. National/federal, regional, and local levels of administration differ in their service and agency definitions, responsibilities and arrangements, and therefore in their

interagency boundaries and the potential connected action that could span them. A major organizational resource challenge is to coordinate service funding in ways that are effective, cost-effective, and fair. Cost-shifting and problem-dumping between agencies will not help children and families. Recognition of economic symbiosis has helped decision makers in some contexts, most notably in the Nordic countries, respond better to needs through intersectoral partnership arrangements, including jointly commissioned programs between the health and education sectors, pooled budgets, and other system-wide initiatives (3,14,15).

FINANCING ARRANGEMENTS

Accessing health care services is not like buying groceries, which is why most high- and middle-income countries rely on prepayment systems of revenue collection. Prepayment is organized through some combination of tax, mandatory and/or voluntary insurance contributions. Prepayment is preferable to out-of-pocket payments. An individual's risk of needing health care is very uncertain, but when the need arises, the attendant costs (of treatment) and losses (of earnings) could be catastrophic. Prepayment contributions pool risks, and have the potential to redistribute benefits toward people with greater health needs. They can also be made progressive, so that poorer individuals pay less for equivalent health care than wealthier people. Out-of-pocket-payment systems cannot achieve such targeting unless accompanied by well-informed systems of payment exemptions that are closely monitored to ensure implementation and prevent abuse.

Prepayment systems have their problems. If there is no charge at the point at which a service is used there may be excessive utilization; this "moral hazard" problem might be addressed by introducing copayments at point of use. Another potential difficulty is adverse selection: In countries relying on voluntary insurance high-risk individuals may be at risk of being denied coverage or face unaffordable premiums. In attempts to cap expenditures, some insurance or managed care arrangements could exclude mental health coverage, with predictable consequences for access, knock-on costs, societal inefficiencies, and inequity. Legal and regulatory measures, including guaranteed enrollment, controls on premium levels, and risk-equalization between insurers, may be needed as countermeasures, as well as safety-net universal coverage guaranteed by public financing.

Whatever the merits of prepayment systems, there are obstacles to their wider use in low-income countries, including the state of the economy, unstable governance structures, and the informality of much employment, making revenue collection impractical. Consequently, out-of-pocket payments dominate in many low-income countries (16), where there may also be some reliance on foreign donors for additional but very limited resources (17).

Financing can be public or private. There are many different financing models, but

public systems will normally rely on some combination of tax and mandatory insurance contributions, while private systems will rely more on voluntary health insurance (VHI) contributions. Voluntary insurance packages may also provide additional coverage for services not included in the basic package of services provided by the public health system. Both systems will make use to differing extent of out-of-pocket payments. Mandatory health insurance systems (often known as social health insurance systems because of guaranteed enrolment and without risk-rated premiums), which are common in parts of continental Europe, are often quasi-public, as funding is often collected and managed by insurance agencies established by government. The picture is however complex; governments have relied on private insurers to offer mandatory insurance packages in some countries for many years, (one example is Germany) while recent reforms in countries such as the Netherlands mean that citizens must now enroll with a private insurer; but the government continues to ensure that all insurers cover the same standard package of care and charge the same premium regardless of individual risk.

Globally, and looking at health systems as a whole, the most common method of financing in OECD countries is tax-based (37%), followed by mandatory insurance (36%), out-of-pocket payments (19%), and voluntary insurance (6%) (18). As far as mental health systems are concerned, almost every country has a mix of public and private funding.

Tax-Based Financing

Many health, education, and other systems are funded from national, regional, or local taxes. Income tax is usually described as progressive because it can be structured to capture progressively larger income shares from wealthier individuals. Indirect taxes such as sales tax tend to be regressive, because poorer individuals generally contribute larger proportions of their incomes. Tax-based systems of health financing are seen as the most progressive and equitable (19). Payments are mandatory, and scale economies can be achieved in administration, risk management and purchasing power (20). For those who advocate health as a right, taxation-based health systems fit the bill, while those with conservative leanings might view such arrangements as an erosion of personal responsibilities and freedom.

Tax-based systems have limitations. Health care funding levels may fluctuate with the state of the national economy, so that when an economy is not doing well, there may be cutbacks to public programs (21,22). Competing political and economic objectives also make a tax-based system less transparent, and bureaucracy can cause inefficiency, reflected perhaps in long waiting lists (although these are also symptomatic of underfunding). Patients tend to view tax-based systems as offering them less choice, but uninsured individuals in other financing systems might argue that they face no choice whatsoever.

With an annual budget of $59 billion the largest publicly-funded health care system in the United States is run by the Veterans Administration (VA), but its focus is on more than nine million enrolled military veterans, and to a lesser extent their families. Most other publicly funded mental health care in the United States that would be relevant to children is delivered through privately owned/managed health maintenance organizations (HMOs), preferred provider organizations (PPOs), or physicians in private practice. In contrast, the tax-funded Swedish health system channels its mental health expenditure through individual counties, ensuring considerable decentralization (18). Child and adolescent mental health systems in countries such as the United Kingdom, Canada, Italy, and Hong Kong are also mainly delivered through public institutions (23).

The tax-based part of the US health system is organized at state level but delivered primarily through nongovernment providers. Medicaid is one such approach, supporting low-income individuals, financed jointly by the federal government and the states, and covering a substantial proportion of all child and adolescent mental health expenditure across the country (3). There have been significant developments in recent years: The Mental Health Parity and Addiction Equity Act 2008 (MHPAEA), expansion of the State Children's Health Insurance Program and the Affordable Care Act (ACA) have made large strides in expanding health insurance, including mental health coverage, to more children from low-income families across the United States. ACA mandates that Medicaid benchmark plans and state-based insurance exchanges cover behavioral health services as part of an essential benefits package (24); Early and Periodic Screening, Diagnosis, and Treatment (EPSDT) services have been extended to all young people covered by Medicaid; and Medicaid covers all children and adolescents under 18 with incomes up to 133% of the Federal Poverty Level (FPL) (25). Furthermore, children in families between 100% and 400% of the FPL qualify for subsidies in the health insurance marketplace. Nonetheless, it remains to be seen whether ACA will provide greater protection for those experiencing mental health issues. The provisions concerning Medicaid are voluntary for state implementation; as of December 2015, there was uptake by 31 states (26). Research also suggests the expansion of Medicaid has not greatly increased utilization rates for people with mental health issues, highlighting the importance of tracking the barriers to mental health care (27).

Mandatory Health Insurance

Health and other systems based on mandatory health insurance generate their revenues from salary-based contributions, either administered and managed by quasi-public bodies (sometimes called sickness funds) or alternatively by private health insurance providers. Employers also make contributions, and transfers are made from general taxation to insurance funds to provide cover for unemployed, retired, and

other disadvantaged or vulnerable people, which is clearly pertinent for families where there is someone with mental health issues. In nearly all countries in Europe that have mandatory health insurance tax revenues are used to cover shortfalls in funding or cover the costs of long-term hospitalization.

Enrollment is usually mandatory, although in some systems, for example, Germany, some citizens can opt out and obtain separate insurance, while in the Netherlands individuals can register as conscientious objectors to mandatory insurance and avoid enrollment. Although premiums are not risk-adjusted, they tend to be linked to income so that pooling allows for redistribution according to need and income.

Entitlement to health care services through taxation or social insurance is commonplace in European countries, and in fact accounts for over 70% of total health spending in most western European states. In some low- and middle-income countries, where tax compliance and collection are difficult, mandatory insurance has been seen as a viable alternative for health care funding (28). However, the link between health financing and employment constrains job mobility and hence economic competitiveness. Both tax-based and mandatory insurance-dominated systems take account of ability to pay and cover vulnerable and low-income groups (19).

Even where universal entitlement under tax or insurance predominates, entitlement to mental health services may be limited, and arguably inequitable. Until 2011 in Austria, mandatory health insurance excluded most mental disorders on the grounds that they were chronic rather than curable. Diagnosis and treatment, including psychotherapy are now covered, but much long-term care including rehabilitation is funded separately through pension fund contributions (29) and private out-of-pocket payments (30). Where services have been shifted out of the health sector, for instance to the social welfare sector, there are greater possibilities for copayments that could inhibit access (31). By contrast, the Netherlands now has expanded coverage for primary and secondary mental health care services within the standard (and compulsory) health insurance package that private insurers must offer. Since 2015 long-term mental health care is now only covered by a separate mandatory long-term care insurance after 3 years rather than 1 year. However, 2015 also saw the transfer of responsibility of mental health services for children to the municipalities; these are no longer funded or covered by the basic insurance package.

Voluntary Health Insurance

VHI can be taken up and paid for at the discretion of individuals (or employers on behalf of individuals) and offered by public, quasi-public, for-profit, or nonprofit organizations. Generally speaking, VHI plays only a marginal role in Europe. We have already noted that in Germany some individuals traditionally could opt out of

mandatory insurance and use private VHI schemes instead. Elsewhere it is used as a complement to tax or mandatory health insurance funding. In France it is predominantly used to cover the costs of co-payments, while in Ireland VHI insurance can provide additional “hotel” services, allow for more rapid care and limit some co-payments for services provided by the public sector health care system. In the Netherlands VHI provides coverage for services not covered by the basic insurance package.

In contrast, VHI accounts for two-thirds of health care expenditure in the United States (32), and 60% of children aged under 18 access health care through private (employer-sponsored) insurance (33). As mentioned above, the ACA updated the MHPAEA 2008, so that group health plans and insurance companies cannot impose treatment limitations and financial requirements (including co-payments and deductibles) for “behavioral health” which are more restrictive than all other medical/surgical benefits (34). There are several other positive changes for young people: Children cannot be excluded from coverage due to a mental health diagnosis; young people can remain on their parents’ insurance policy until age 26; there are no annual limits on the amount insurance providers can pay for basic health care; and lower deductibles (25).

Despite these changes, obstacles still remain. Some groups will not benefit from ACA, including those in employer-sponsored plans that do not offer behavioral health benefits, as well as undocumented immigrants (33). It is also essential that delivery systems such as Accountable Care Organizations take into account the behavioral health perspective when facilitating integration within the private insurance system (24). As far as children’s mental health services are concerned, because they have been underdeveloped and poorly coordinated in some states for many years, the effect of ACA has been modest in some localities, although there appears now to be greater recognition of the consequences of inadequate service systems and the need to take action (35).

People individually purchasing insurance have lower bargaining power, which affects the premium paid and/or the benefits covered. Inherent also in this financing system are disadvantages like adverse selection and cream skimming: Higher-risk groups (such as those with mental health issues) may find insurance unaffordable, especially as mental illness is more prevalent among lower income groups, and lower-risk groups may feel that their own premiums are too high. Most insurance plans also exempt existing conditions from the benefit packages.

Out-of-Pocket Payments

In prepayment systems, out-of-pocket payments may be co-payments (specific amount to be paid), coinsurance (agreed percentage of expenses) or deductibles (agreed amount to be paid before insurance kicks in). Though the objectives for introducing

out-of-pocket payments differ, the impact remains common everywhere in adversely affecting access and equity. An argument for out-of-pocket payments is that they discourage unnecessary service use (moral hazard) and create price sensitivity that might help direct patients to more cost-effective and appropriate treatments. On the other hand, out-of-pocket payments might defeat the very purpose of cost efficiency, as delayed treatments might substantially increase longer-term costs. Given the stigma associated with mental health issues, their chronicity, and the damage they can cause, heavy reliance on out-of-pocket funds is surely inadvisable.

A 2011 study of six western European countries found 41% of citizens paying some out-of-pocket charges for specialist mental health services, rising to 87.9% in Belgium and 61.7% in Italy (36), although some will get reimbursed under current insurance schemes. They are even more prevalent in parts of central and eastern Europe (37,38), and are often the only means of health finance in low-income countries (39). In the United States, Medicaid expansions between 1998 and 2011 significantly lowered out-of-pocket spending for mental health amongst adults (27).

Commissioning

In order to move revenues collected from taxes or insurance premiums to service providers, a variety of commissioning or purchasing mechanisms can be used. Provider reimbursements can be retrospective (such as FFS) or prospective (capitation and/or fixed budgets). Historically, FFS arrangements dominated health care commissioning, and although they encourage productivity, they also perversely encourage resource consumption through unnecessary visits, diagnostic investigations, and hospitalizations, and so push up overall costs. Consequently, prospective payments have increasingly been substituted, particularly as part of managed care developments, to encourage cost consciousness among providers. Capitation is one such method: A fixed payment is made for a defined set of benefits (in input and/or outcome terms). It encourages efficiency, but risks adverse selection and cream-skimming. Providers might narrow their practice and undermine the objectives of managed care to provide primary and preventive interventions (40). Such behavior shifts costs onto other providers. Some prospective payment methods use diagnosis-related groups (DRGs), a case-mix classification system that groups patients with a similar clinical diagnosis and treatment process to calculate the funds to be allocated. DRG-based pricing can help save costs but to get around this providers might resort to up-coding or “DRG creep,” which is the practice of billing using a DRG code that provides a higher payment rate than the DRG code that accurately reflects the service furnished to or needed by the patient.

Some public financing systems adopted commissioning methods from the private insurance market, with emphasis on managed plans. In the United States earlier experience with Medicaid, for example, showed that enrollment in some form of

managed care shifted the balance of treatment away from inpatient treatment (41), but perhaps increased the risk that seriously ill children would be undertreated (3). A study comparing three different arrangements (FFS, HMO, and carved-out managed care plans) found no significant differences in access rates, but the FFS plan was favorable for children with an increased risk profile (42). Another study found that satisfaction ratings were much higher in Medicaid for FFS than for managed plans (43).

TARGETING, EFFICIENCY, AND EQUITY

There are never likely to be enough resources to meet all mental health needs. Choices must be made. For example, to what extent should child psychiatric services be delivered from a hospital base or from a community clinic? If there are more children and adolescents needing to see specialist staff than there are treatment sessions available, who should get priority? What proportion of a mental budget should be diverted away from treating identified needs in order instead to uncover previously unrecognized needs? What investment should be made to support a broader health promotion strategy? When does it make sense to stop treating or supporting one particular child or family and to use the time to initiate a treatment program for a newly referred child?

Decision makers—from those who control the budgets to those who actually deliver the services—need to be clear about the basis upon which they choose one option over another. In a world that is increasingly seeking evidence-based approaches to policy and practice while recognizing resource scarcity, a number of resource-related criteria are likely to be invoked to guide such decisions, maximizing therapeutic impact from available resources, integrating more children with behavioral problems into mainstream education, broadening access to effective therapies, improving fairness in what families have to pay for treatment, and improving targeting of services on needs. Many of these resource-related criteria fall into two groups: efficiency and equity.

Efficiency

Efficiency means achieving the maximum effects in terms of services delivered or outcomes achieved (such as needs met, wants satisfied, or quality of life improved) from a specified volume of resources (such as an annual budget).

Many factors might prevent a mental health system from being fully efficient. Perhaps too many resources are tied up in the administration of the system itself: Are there, for example, too many managers supervising the people who actually deliver treatment? Another source of inefficiency could be that resources are used in inappropriate combinations: A child psychiatrist is likely to be more effective, for

example, if they can access a range of therapies supported by a multidisciplinary team. Or there may be poor target efficiency in that available services are not provided to the people with greatest needs, because insufficient efforts are made to identify and prioritize needs or to encourage families to seek treatment. Another reason for inefficiency could simply be that little is known about the relationship between resources, services, and outcomes.

Cost-Effectiveness Evidence

When considering whether to use or recommend a particular treatment for a specified problem, decision makers must first get an answer to the central clinical question: Is the treatment effective in improving health and quality of life? They will then usually want an answer to the second question: Does the treatment achieve the outcomes at a cost that is worth paying? Not surprisingly, the second question—the economic question—can generate howls of concern that it encourages rationing or in some way denies people access to services or better quality of life.

Cost-effectiveness analysis compares the two parts of the chain in Figure 1.7.1 that link what gets spent (resources and costs) to what is achieved (outcomes). While it is always likely to be necessary to reformulate the clinical and economic questions in ways that make them answerable with empirical research, we should not forget their inherently straightforward intent.

Given what we have already discussed in relation to the broad mixed economy of provision and financing, it is obvious that we will generally need to view both costs and outcomes in quite broad terms:

- There are many inputs to a child and adolescent mental health system—health, social services, education, criminal justice, and so on—plus economic impacts in terms of lost productivity, premature mortality, and family burden. Each of these has associated costs (5,8).
- Good mental health care is not just about tackling clinical symptoms, but about improving someone's ability to function in ways that are valued by them and about promoting quality of life. There are also likely to be impacts on parents, siblings, classmates, and communities.

There have been relatively few studies of cost-effectiveness of interventions for children and adolescents with mental health problems. Most have been undertaken in North America, Western Europe, or Australia. This geographical unevenness needs emphasis because the results of economic evaluations may not transfer readily from one country to another: Differences in health systems, financing arrangements, incentive structures, and relative prices hamper generalization.

A recent review of the international literature found 67 studies reporting costs or cost-effectiveness analyses, with half coming from the United States (44). The most commonly studied areas were autism spectrum disorder (23 papers), attention deficit

hyperactivity disorder (15 papers), conduct disorder (7 papers), and anxiety or depression (8 papers). The great majority were narrowly focused on health care costs (which is a major limitation, given the important service contributions from the education and social care sectors, the impacts often on criminal justice, and the unpaid contributions from families). Full cost-effectiveness analyses remain relatively rare, however.

Equity

Equity relates to the distribution of outcomes, access, and payment. One very relevant equity question is whether individual financial contributions are linked to ability to pay, indeed whether there needs to be a redistributive effort so that families with lower incomes contribute proportionately lower amounts. We touched on this question in discussing financing, and arrangements can be made to improve distribution. Equity in relation to outcomes is another matter. Certainly, equity in final outcomes is a laudable but ambitious goal, primarily because those outcomes are influenced by so many factors over and above the resources devoted to mental health care, including socioeconomic position, family resources and dynamics, housing and community environments, and individual lifestyle and personality. Consequently, equity in access—perhaps expressed as equal access to treatment for equal need—is more frequently discussed as a policy criterion, yet is still of course very hard to achieve.

It is clear that rates of service utilization by children and adolescents with mental health problems remain low across many countries, and that patterns of access are unevenly distributed (45,46). From an egalitarian standpoint it could be argued that utilization should not be influenced by "extraneous" factors such as ability to pay or geographical location.

Why do children, adolescents, and families not use services? One enduring reason is the stigma widely associated with mental illness. Another is the low rate of identification of needs. A third, obviously, is inability to pay for treatments. Many factors therefore contribute to inequality and numerous solutions have been propounded, including actions to improve public awareness and reduce discrimination, and redistributive financing arrangements that are less disadvantageous to poor families.

BARRIERS AND OPPORTUNITIES

Even when there is an evidence base—that is, even when there is a good appreciation of how to enhance child and family health and quality of life, or improve system efficiency, or improve the distribution of payments or access—there could be resource barriers in the way (47). These barriers challenge child and

adolescent mental health systems across the world.

Resources

One of the most insidious and seemingly insurmountable barriers is resource insufficiency. This is clearly a major issue for countries where the proportion of national income devoted to health care is low, as in most low-income countries, or where the proportion of the health budget allocated to child and adolescent mental health is minimal. Without funds, it is difficult to build any kind of service system. Resource insufficiency leads inevitably to shortages of skilled staff (3,45) and difficulties in recruiting and training appropriate personnel. Such shortages might energize the search for treatment modalities that make more cost-effective use of what is actually available, but there are limits to what can be achieved.

Increasing the resources available for child and adolescent mental health care would help overcome these challenges. But even when resources are committed, available services might be poorly distributed, available at the wrong place or time relative to the distribution of needs. They may be available only if delivered by specialist clinics or particular schools, or concentrated in major cities, or available only to certain population groups (usually those with higher incomes). This resource distribution barrier is often related to the fundamental way in which a health or education system is financed or structured. In centrally coordinated systems, resources could perhaps be allocated according to need, but systems built on private insurance and out-of-pocket financing have few such opportunities.

Inappropriate Use of Services and Personalized Care

A more general difficulty is resource inappropriateness: Available services do not match what is needed or preferred. Treatment arrangements may be too rigidly organized, leaving service systems unable to respond to differences in individual needs or preferences, or to community circumstances. Such inflexibility is common when there is scant information on population or individual needs, or when families have few opportunities to participate in treatment decisions. There may also be a deep-rooted reluctance to move away from hospital-based services.

More research is needed on less conventional evidence-based therapy such as mHealth (online therapy), mindfulness, and various community-based interventions. For example, a recent study of a parenting intervention for reducing anxiety in children has shown encouraging cost-effectiveness results (48). Personalization of treatment might include using personal budgets, giving young people and their families more control over how their health and other needs are met. This has been trialled in the United Kingdom, for example (49). Ultimately, better quality services and improved outcomes will require input from mental health service users and

carers—and a framework to support such engagement (50).

Co-ordination

A linked challenge is resource dislocation. Services may potentially be available to meet individual and family needs, but they are poorly coordinated (13). Such a situation can be compounded by professional rivalry, performance assessment regimes, stultifying bureaucracy or "silo budgeting" (resources held in one agency's "silo" cannot be allocated to other uses), and some forms of managed care. Improved coordination might be achieved by reducing budgetary conflicts between agencies, rewarding efficiency and equity improvements, and encouraging individual and family participation in decision making. These arrangements have their own (transaction) costs, of course, and a careful spending balance must be struck between using resources to deliver services and using them simply to coordinate. In England, it is hoped that Local Transformation Plans, which encourage joined up working between national government and local agencies, will promote greater integration of children's services—thus providing a more responsive and efficient system for supporting children's mental health (51).

Short-Term vs. Long-Term Effects

The timing problem can be quite insidious. For a start, most intended improvements to practice take a long time to work their way through to improved health outcomes, cost-effectiveness gains, or fairer access. Moreover, evidence for improved practice may have been gathered under experimental circumstances and the advantages suggested by research may not actually get realized in real-world settings. There could be transitional or longer-term difficulties recruiting suitable professionals, or opening new facilities. Decision makers must also be encouraged to think long, for the immediate consequences of many interventions could be modest, but the long-term benefits immense (52–54).

Stigma and Attitudes

Negative and stigmatizing attitudes towards mental illness can put up other barriers, leading to disadvantages in relationships, education, and work (55). Such attitudes may also contribute toward premature mortality for individuals with comorbid mental and physical health problems (56). There have been attempts to alleviate experienced discrimination such as through social contact (57), and through anti-stigma campaigns such as Bring Change 2 Mind or Time to Change in the United Kingdom, but greater research is needed for determining the best intervention for reducing stigma in young people (58).

New Technologies

Attention must briefly be given to the barriers and opportunities linked with social media, the internet and mobile/cell phone technology. Whilst the online world has its dangers (unmonitored online forums, cyberbullying, unwanted sexual messaging, psychosocial risk factors (59)), there are also opportunities: individual choice (of support), mobile phone apps for symptom monitoring (60), information on mental health conditions, and complementary interventions to cognitive behavior therapy (61). Workforce shortages, geographical barriers to service provision, and the difficulties of engaging with certain minority groups could see e-health innovations providing cost-effective benefits, although problems of equity may arise if the already disadvantaged poorer population cannot reap the benefits of high-tech interventions (62).

CONCLUSION

Child and adolescent mental health systems—interpreting this term broadly to include health, education, social work, and criminal justice components—are often in a state of flux. It may be a shift of emphasis from inpatient to community-based services, or the broadening of treatment eligibility criteria, or the expansion of insurance coverage. It could be the reconfiguration of multiprofessional staff teams, or new school-based proposals for identifying need. Changes of this kind usually raise economic questions. How are these initiatives to be financed? What cost implications will they have? Are they affordable? Will they prove cost-effective? What will they imply for the distribution of payment, access, and outcome?

There are many ways to raise and distribute funds for child and adolescent mental health services, but there is no agreement on the best form of prepayment system, and the balance between tax and different models of insurance based funding. It is also important to consider whether out-of-pocket payments create appropriate incentives, or whether fee-for-service, capitation, or some other mechanism is the best way to pay service providers. There is growing experience of using these approaches, and growing evidence about what they might imply in particular for children and families affected by emotional or behavioral problems.

Given the comparatively high prevalence of these problems among poorer groups in the population and the often high costs of accessing effective treatments, governments need to make commitments to redistributive policies. They need to set in place the structures that encourage efficient and equitable links between the fundamental aims of improving the lives of children, adolescents, and families; the services and interventions that can deliver those improvements; and the financing mechanisms and purchasing systems that get the funds to providers. And they need to do so across many service sectors—certainly looking at specialist mental health,

general medical care, education, social work, supported housing, social security, and criminal justice.

SECTION II

A DEVELOPMENTAL FRAMEWORK

2.1 NORMAL DEVELOPMENT

CHAPTER 2.1.1 ■ THE INFANT AND TODDLER

LINDA C. MAYES, WALTER S. GILLIAM, AND LAURA STOUT SOSINSKY

The role of child psychiatry in care of infants and toddlers is expanding especially as the diagnostic nosology for serious early development disorders such as autism or attachment disorders becomes increasingly refined. Further, as child psychiatrists collaborate actively with pediatricians (1), they often are called upon to assess infants and toddlers for apparent developmental delays, behavioral difficulties, or parent–child problems. The interface between child psychiatry and pediatrics also means child psychiatrists may consult with parents during their pregnancy or as they anticipate their older child's response to the birth of a new sibling. As child psychiatrists also provide consultation to a range of child care and early education settings, they are more often consulting with parents about child care decisions and settings. Each of these consultative settings requires that child psychiatrists have a solid understanding of normative early development. In this chapter, we provide guidelines for thinking about normal early development and the basic phases of infant and toddler development especially as these are relevant to the clinical practice of child psychiatry. We also provide an overview of salient issues regarding the environments of infants and toddlers again as these are relevant to clinically salient issues in the development of young children.

Most scientists and clinicians define the periods of infancy and toddlerhood as being the first 3 years of postpartum life. More specifically, infancy refers to the time before the beginning of expressive verbal communication that occurs at about 18 months. The developmental shift that occurs at this time has a dramatic transformational impact on the child's ability to reason cognitively, deepen elaborate social relationships, and mediate emotional experiences linguistically. Toddlerhood is a period of increasing autonomy in which the child uses his or her new skills to explore their world, physically, cognitively, and socially. Regardless of the exact chronological time frame, infancy and toddlerhood encompass the most rapid and contextually transactional period of neurodevelopmental change throughout the postpartum life span. Therefore, all clinical work in child psychiatry with infants and toddlers is framed by the context of rapidly changing, growing systems that may be in or out of synchrony with one another.

NORMATIVE DEVELOPMENTAL FORCES

Development is characterized by processes by which each individual uniquely adapts and integrates his or her own nature with the opportunities and limitations of his or her experience across time. The developmental transactional ecological framework posits a child's behavior at any point in time as a product of reciprocal transactions

among the child's characteristics (genetic/biological/physical, cognitive/linguistic, and social/emotional competencies) and the caregiving environment (dynamic interrelationships among child behavior, caregiver responses to such behavior, and the dyadic relationship) and the broader ecological context (multiple levels of social organization, including family, neighborhood, and child care) (2–7).

Developmental psychopathology is similarly characterized by patterns of behavioral adaptation over time and in context, rather than by static, isolated, or domain-specific problems (7–9). The average environment often can sufficiently compensate for problems when they occur. But when a child's unique needs or difficulties are present in an environment lacking adequate nurturance and support, they combine to produce "initial patterns of maladjustment which then spin their way into diagnosable pathology" (7).

Interacting Factors in Development

There are several interacting factors that drive or moderate developmental processes. Indeed, clinical assessment of infants and their families represents a process of gaining a better understanding of these interacting forces. Five specific areas are discussed: (a) the interaction of innate and experiential factors, (b) maturational processes, (c) the essential role of relationships with others for healthy development; (d) the broader context of relationships and the environment; and (e) developmental stages and critical or sensitive periods. While each of these areas is interrelated, there are points that are unique to each.

The Interaction of Innate and Experiential Factors

The interactive balance between innate and experiential factors is a well-worn controversy in developmental science, and even now it is possible to find proponents emphasizing the singular importance of one over the other. Rarely are these issues clearly distinguishable in a clinical evaluation. At the least, infants bring a set of innate capacities that influence how they respond to the environment and how it responds to them. The clinician is always faced with considering how intrinsic and extrinsic factors have interacted to contribute to an infant's developmental difficulties or strengths. Infants are more vulnerable to developmental dysfunction, even with a supportive environment, if there is biological dysfunction, as in genetic disorders or severe prematurity. Conversely, even "well endowed" infants are at risk for developmental dysfunction if their environment provides inadequate or inconsistent nurturing. A combination of an impoverished or dangerous environment combined with biological or genetic risks is a significant predictor of developmental dysfunction, and as the number of risk factors increase so increases the likelihood for poor outcomes (10,11). Indeed, genes, the environment, and the interaction of these

two forces each play a large role in cognitive development (12). This transactional model of child development, which stresses the dynamic interplay between individual- (genes, experience) and contextual-level (aspects of environment, culture) factors, is the prevailing paradigm (13) and there are now several compelling examples of apparent gene–environment interaction including, for example, in utero effects of stress on later cognitive development (14).

Maturational Processes

Depending on the clinician's frame of mind, maturation, or the progressive unfolding and differentiation of intrinsic capacities, presents either a complication or a challenge in the process of developmental assessment. Infants change rapidly, and the appearance of behaviors and responses can be highly variable despite certain expected sequences. Also, although very young infants begin life in a relatively undifferentiated state, within the first months, perceptual and motor systems differentiate rapidly. Implicitly, a stage-based model of infant development guides much of clinical perspectives by acknowledging that sequences of development *generally* are based upon orderly maturational steps that have been well described and defined. This sequence and the knowledge of when children typically achieve certain skills can be used to establish norms, against which an individual infant's developmental skills can be contrasted. As Provence (15) has stated, "Maturation … is a necessary construct, an invisible process represented by observable behaviors."

As described above, environment, genetic predisposition, and the interaction of both can alter maturational forces significantly. For example, we expect grasping patterns to follow an expectable, regular sequence of neurologic maturation but know that the timetable for infants' use of a particular grasp to hold a toy or explore a box is individually variable and can be highly related to the infant's exposure. Or, although the infant may have the neurological capacity for a responsive smile and the perceptual–motor integration to extend his or her arms toward an adult, experience in interaction with the environment is a necessary factor for such observable behaviors to emerge. Also, it is true that variants of typical maturational processes exist that are not necessarily associated with later problems. For example, it is typical for infants to learn to crawl on hands and knees at 8 to 9 months old and then walk at 12 months. However, various alternative pathways of infant locomotion are fairly common and are not necessarily related to underlying problems, and researchers have long known that age of walking alone is not a good predictor of developmental outcomes (16).

It is important to draw a distinction between developmental processes that are primarily delayed versus those that represent a qualitative deviation from the typical progression of skills. For example, some infants and young children present a pattern of development that approximates the typical orderly progression of developmental skills, but are nonetheless developing along that track at a pace significantly behind their same-age peers. Others, however, may evidence patterns of development that

are substantially different from the normal progression or show signs of qualitative differences in neuromuscular development (localized or diffuse hypotonia, abnormal reflex patterns). Significantly deviant patterns of development appear to be more common in children whose overall development is very delayed relative to chronological age expectations.

Relationships

It is impossible to overstate the role of human relationships in development. The essential role of stable and nurturing human relationships is well established and universally acknowledged among researchers (17). However, most formal infant assessment techniques were developed to focus exclusively on the measurement of maturational forces, as if assuming that development proceeds relatively independent of environmental input. Thus, it is important to emphasize *that every infant assessment* must consider the other individuals in that infant's life. Understanding normal, delayed, or deviant development requires some understanding of the infant's experiences with adults. The younger the child, the more central are such individuals to the child's safety and total well-being. Such serious events as traumatic separation, physical abuse, witnessing violence, deprivation, loss, and neglect often have devastating effects on a child's development (18). Moreover, less extreme variations in children's environments have profound effects on every aspect of early development, with relationships and interactions with primary caregivers being of acute importance in the very early years.

Understanding the early environment in which infants and toddlers develop is a vast topic that encompasses individual differences in parenting style, the impact of parental psychopathology such as depression, family disruption such as divorce, and how parents adapt their behaviors to the emerging developmental skills of the infant, each area of extensive clinical scholarship and research. In this section are highlighted the areas most relevant for child psychiatrists beginning to evaluate a young child or work with the parents of an infant or toddler.

Relationships and interactions with primary caregivers, most often the mother and/or father, directly affect and dynamically interact with multiple domains of child development. These domains include attachment and social-emotional development; behavior, cooperation, and development of morality; early learning, exploration, and cognitive and language development; and health and physical development. Parents also indirectly transmit to their children, through their impact on caregiving behaviors, the effects of more distal environmental factors such as poverty (19–21), parental life circumstances (21,22), and parental beliefs and attitudes (23). Parents can also shape their child's environment indirectly through provision of stimulating and supportive social and material resources in the home environment, through choice of neighborhood, and, most crucially in early childhood, through their decisions regarding nonparental child care (21,24–26). Furthermore, the same distal

environmental factors, like poverty, that affect parenting also limit parents' ability to choose and shape their child's home, neighborhood, and childcare environments (17,20,21,25,26).

Infants are strongly motivated and primed to develop attachments with adult caregivers to ensure close, protective, and nurturing contact. When parenting (or primary caregiving) is reliably sensitive and contingently responsive to a child's cues and needs, the child is more likely to develop a secure attachment. Secure attachment behaviors include using the parent as a secure base from which to comfortably explore, monitoring and seeking proximity with the parent, seeking contact eagerly after separation or if frightened, and evidence of trust and delight in the parent. When parenting is detached, intrusive, erratic, inconsistent, or rejecting, children are more likely to develop an insecure attachment, characterized by disrupted play, preoccupation with the parent's presence, avoidance or resistance to contact and distress or anger at reunion after separation, or difficulty being comforted. Secure attachment has been associated longitudinally with development of social and emotional competence, a child's confidence and sense of efficacy in novel or challenging situations and ability to manage stress, and greater self-efficacy, and is shown to set the stage for future positive relationships with others (16,27,28).

Adequate care and nurturing for an infant involves a balance among gratification, comfort, and support and the frustration inevitable in all developmental phases. Adequacy in caregiving, difficult as it is to define, generally includes attempts to mediate painful, tension-producing situations and to adjust the balance between comfort and frustration. The appropriate balance varies depending on the child's age. For example, the infant's frustration at not being fed immediately is different from the toddler's frustration at being unable to reach a favorite toy, and each requires a different response from the parents. In one instance, frustration may produce a painful, tense state; in another, it may lead to an adaptive solution that enhances further learning and appropriate individuation and independence.

Parenting is associated powerfully with other domains of child development beyond attachment, although the lines between various parenting behaviors and areas of child development are blurred by dynamic transactions and integration over time. Sensitivity, contingent, appropriate responsiveness, and consistency are associated with all areas of social-emotional development (including competencies such as sustained attention, compliance, empathy, prosocial peer interactions, and emotion regulation) and also support children's early learning. Parents promote their child's language and cognitive abilities when they understand their child's current abilities and structure learning opportunities accordingly, provide a rich verbal environment, and adjust their support and stimulation as the child's capacities emerge (16,29).

Furthermore, while encouragement rather than restriction of exploration is helpful, limit setting and consistent and firm standards are also important especially for a toddler's development of cooperation, behavioral control, and sense of conscience.

Authoritative (rather than harsh or permissive) setting and enforcement of limits, incentives, and punishments, modeling of desired behaviors, and consistent routines all positively affect child's behavioral development. Rather than a static "parenting style," these behaviors are dynamic, adjust for changing child characteristics, and involve give and take. Toddlers' developing cognitive capacities integrate parental expectations and standards, in turn affecting development of self-regulation, conflict management, empathy, cooperation, and awareness of the feelings and perspectives of others (16,29).

Often clinicians are not always dealing with gross parenting deficits or failures, such as in serious abuse and neglect (30). For many infants and young children, there are crucial experiences that may have adverse effects that are much harder to identify. For example, we are only beginning to understand the critical effect of maternal depression in the first month to 1 year, when the mother is psychologically and sometimes physically unavailable to her infant (22,31,32). A growing body of research on the issue of caregiver mental illness, however, suggests that serious psychopathology in caregivers can significantly alter dyadic and familial interaction patterns, which in turn lead to altered developmental courses for infants. Caregiver psychopathology is a forceful example of how parental life circumstances might alter parenting and, thereby, infant and toddler development. Other factors internal to the parent—such as parenting stress (negative perceptions of child behavior, the parent–child relationship, and the self as parent) and child-rearing beliefs (nonauthoritarian or progressive child-centered child-rearing beliefs, such as belief that children learn actively vs. traditional or adult-centered child-rearing beliefs, such as approval of uniform treatment and encouragement of obedience to authority)—also shape parenting behaviors. Life circumstances, such as single parenthood, low parental education, substance abuse, and, most pervasively, poverty, can strain the parent's ability to respond sensitively and contingently to their infant's cues and needs (17,20,21). Caregivers, however articulate and enlightened, may be unaware of their own difficulties in responding to their infants, or of how their mood states, worries, and frustrations affect their parental responsiveness. It is at this level that the importance of establishing a working relationship between parents and evaluator is clearest.

Broader Context and Environment

The early environment in which infants and toddlers develop is influenced by the broader ecological context. The broader ecological context includes the home environment, other caregiving environments such as nonparental child care, broader family circumstances and risks, and the neighborhood. These contextual influences on child development may be direct, as in the case of a nonparental caregiver's interactions with the child, indirect, as in the effect of poverty on parenting behaviors and available resources, or both direct and indirect, as when poverty limits a

parent's child care choices, thus exposing the child to poorer quality child care.

The Home Environment. Within the family setting, the materials, activities, and transactions that are supportive of early learning have been shown to be associated with children's IQ, cognitive and language development, and later school performance (24). The supportiveness and stimulation of home environments vary greatly by family socioeconomic and ethnic status, and such variations, even in the very early years, demonstrate differential effects on child outcomes. Parents' provision of social resources, such as opportunities to interact with peers, also influence child development (17,20,21).

Understanding a young child's typical "environment" is a crucial part of any thorough child psychiatric assessment. Who cares for the infant during the day? Is there a live-in nanny or do the parents take their baby to grandparents, older aunt or uncle, or a family childcare program neighbor? Often these individuals may actually spend more direct care time with a young infant than parents themselves and in addition to being able to provide extensive history about the infant's daily routines and emerging skills, are also important attachment figures for the infant. Furthermore, infants and toddlers adapt differently to different caregivers and not uncommonly, may behave differently with different adults or show fewer or more symptoms depending on the adult caring for them at the time. Hence, it is very important to have multiple informants regarding an infant or young child's development and behavior when she or he is being evaluated.

Nonparental Child Care. A very young child's relationship and interactions with his or her parent (or primary caregiver) may be most salient and central to early development, but other caregiving experiences also impact child well-being. For the vast majority of young children today in the United States, nonparental child care is "second only to the immediate family" as a developmental context (17). The impact of relationships and interactions with nonparental childcare providers on child development is similar in many ways to the influence of parental relationships. Children can form attachment bonds with nonparental caregivers and receive supports for early learning and language development. In addition, in many settings, young children experience peer interactions and a school-like environment.

To put the scope of child care environments in context, about 20.4 million young children are regularly in care by someone other than their parents, largely due to the vast increase in employment of mothers of young children in recent decades. The largest increase in the last decade and a half has been in child care use by infants and toddlers, with nearly half of all children under the age of 3 in the United States spending some time in child care (17). Child care settings, which vary widely, fall into four broad categories, listed from the least to the most formal: relative care, in-home nonrelative care (nannies, au pairs), family day care, and center-based care. Parents more often utilize home-based care for infants and toddlers, in part due to

greater preference, flexibility, and availability, and sometimes to lower cost. Almost one-third of infants and toddlers in care are in family day care homes.

The quality, as well as the quantity and type, of child care experienced by young children contributes to child development. High quality child care is characterized by warm, responsive, and stimulating interactions between children and caregivers. For example, high-quality interactions are characterized by caregivers who express positive feelings in interactions with children, are emotionally involved, engaged, and aware of the child's needs and sensitive and responsive to their initiations, speak directly with children in a manner that is elaborative and stimulating while being age-appropriate, and ask questions and encourage children's ideas and verbalizations. Structural and regulatable quality features of the setting, including ratio of children to adults, group size, and caregiver education and training, act indirectly on child outcomes by facilitating high-quality child–caregiver interactions. To illustrate, it would be difficult for even the most sensitive and stimulating provider to provide high-quality interactions with each child if she was the sole caregiver of 10 toddlers (33). Furthermore, given the unique developmental characteristics of infants and toddlers, a specific focus on developing and supporting relationships between young children and their caregivers can give babies opportunities and time to establish strong relationships with their child care teachers (34–36).

Disentangling the effects of nonparental caregiving on child development is complex, as the type, quantity, and quality of child care to which children are exposed is not random but selected by parents. Recent research, especially the NICHD Study of Early Child Care and Youth Development, have made strides in this direction (33). Furthermore, as parents choose child care, it can be considered indirect parenting (even by many parents) (37), and is another important avenue by which parents impact their young children's early development. The magnitude of the effects of parenting and family factors on child development is about twice that of child care factors (38). However, after adjusting for family characteristics, child care retains unique influence on child development, with one study finding child care's influence up to about half the magnitude of the effect of parenting. The greater strength of effect of parenting is to be expected, as biologic parents share genetic characteristics with their children, which most nonparental child caregivers do not (or share less genetic similarity, in the case of grandparents or other relatives). Plus, parents (whether biologic parents or not) are typically stable, consistent, central presences in their children's early years, whereas most nonparental caregivers come in and out of the children's lives, and many times children have multiple caregivers (and even multiple arrangements) simultaneously. The effects of child care characteristics on child development are highlighted next.

A child's experience of child care per se is not related to better or worse outcomes for children compared to child's experience of exclusive maternal care

(39). Earlier research suggested that child care exposure in the first year of life may interfere with the mother–child attachment bond (40). However, one subsequent study demonstrated that only when combined with low maternal sensitivity and responsiveness did poor-quality child care, larger quantities of child care, or multiple child care arrangements predict greater likelihood of insecure attachment (41). Beyond the question of attachment, the longitudinal effects of child care quality, quantity, and type on child outcomes have been examined extensively, demonstrating that child care quality is a consistent and modest predictor of child outcomes across most domains of development, child care quantity is a consistent, modest predictor of social behavior, and child care type is an inconsistent, modest predictor of cognitive and social outcomes, adjusting for family factors (parental income, education, and race/ethnicity, family structure, parental sensitivity; 42,43). In general, children who experienced higher quality child care performed better than other children on cognitive, language, and academic skill tests and, at some points in early childhood, were rated as showing more prosocial skills and fewer behavior problems and negative peer interactions.

The disturbing fact is that, despite the importance of high-quality child care for child development, several large studies have found that most child care is of "poor to mediocre" quality (33,41,42). Observed quality in infant and toddler settings is low in general and often lower than in preschool settings (44,45). In one study, only 14% of centers (8% of center-based infant care) were found to provide developmentally appropriate care, while 12% scored at minimal levels that compromised health and safety (40% for infant care) (41). Similarly, in another study, 58% of family day care homes provided adequate or custodial care, and only 8% provided good care (42). Unfortunately, children with the greatest amount of family risk may be the most likely to receive child care that is substandard in quality. However, many children from lower risk families also receive lower quality care, and despite their advantages at home, these children may not be protected from the negative effects of poor-quality care (46).

In addition, changes in nonparental care can be disruptive for young children, and are important factors for clinicians to consider in assessment and treatment. In one early study, children who changed caregivers before 2 years of age were less securely attached to their caregivers and were more aggressive compared to children who remained with their caregivers (46). Toddlers 18 to 30 months of age who experience multiple caregivers or multiple child care arrangements over the course of a day are more likely to have more behavioral problems (47,48).

For most parents, finding child care that they can afford, access, manage, and accept as a good environment for their child is a very difficult process, and one many parents find distressing (25,49). Not only is affordable and accessible child care hard to find, many parents are worried about how their child will fare in child care. Many parents worry that their child will feel distressed by group settings, will suffer

from separation from the parents, or will even be subjected to neglect or abuse. This worry is especially likely among low-income parents with fewer family and community resources to draw upon (50). A smaller proportion of parents may think of child care only as babysitting, and may not consider consequences for their child's development so long as the child is safe and warm. These parents may be less likely to select a high-quality child care arrangement, which is especially problematic, if the family is facing socioeconomic challenges that already place them at risk of receiving lower quality care for their children (51). Complicating the problem, many parents feel that little organized, helpful professional guidance in choosing child care is available (25). Furthermore, parents are the purchasers but not the recipients of care, and are not in the best position to judge its quality. In addition, many parents are first-time consumers of child care with little experience and very immediate needs, selecting care in a market that does little to provide them with useful information about child care arrangements (50).

Importantly, children may be in the same child care setting, but they may have very different experiences depending on their individual characteristics, dispositions, and even physiological responses to the environment (52). Parents and child mental health practitioners need to know more about the individual child's own environment and how the child acts and interacts in that environment, and must do so in micro-contexts throughout the day (i.e., morning and afternoon, during transitions, during group time and individual time, with each caregiver if more than one, etc.; 53).

Child professionals may be many parents' only source of professional consultation regarding their child. Child psychiatrists can emphasize the importance of high quality care for an infant's or toddler's development, describe how it looks and provide referrals and information on how to find and select high-quality child care. Furthermore, child psychiatrists can help parents determine how to adjust child care arrangements to best meet their child's specific needs (eating and sleeping habits, enhanced language classrooms). Parents may also request a child psychiatrist's assistance in evaluating a program for their child. Child psychiatrists may find it important to see an infant or toddler in their child care setting and to meet the teachers and staff. Increasingly child psychiatrists are called upon to serve as consultants to such settings, both to evaluate individual children and also to consult to the teachers and staff about program development and continued staff education.

Developmental Stages and Critical Periods

Historically, theories of development have conceptualized the phenomena as primarily either quantitative or qualitative. A quantitative conceptualization portrays development primarily as a continuous orderly accumulation of skills, dependent on the mastering of prerequisite skills. Qualitative conceptualizations, in contrast, stress the importance of various developmental stages that are each qualitatively different and represent a marked shift in the manner in which the person perceives,

understands, and interacts with the environment. In short, the quantitative conceptions represent development as a continuous process, whereas qualitative theories propose that development is a process marked by periodic discontinuities or reorganizations. The concept of developmental stages involves such theories as Freud theory of psychosexual stages, Erikson theory of psychosocial stages, and Piaget's theories of cognitive stages. Clinically, the concept is a valuable one in that it provides schemata for understanding development. Extant research provides some support for both conceptualizations, and the developmental continuity versus discontinuity debate continues.

Research suggesting the existence of certain *critical periods* in human development has provided some support for conceptualizing development as occurring in qualitative different stages. The concept of critical periods for the optimal development of different functions suggests that certain capabilities are optimally mastered at certain times, and difficulties arise when this optimal period is disrupted. Although the concept of critical periods was first clearly established in animal models, it has been demonstrated in humans, especially in the areas of social competence and language acquisition. Indeed, it appears clinically true that when the critical period passes without optimal organization of a given function, mastery is fully achieved with far more difficulty, if ever. It is also a clinical truism that when a function is newly emerging, it is most vulnerable to environmental stresses. This statement is supported by the common observation that an infant may stop talking if hospitalized just as the first words appear. Similarly, for an infant, chronic environmental stressors may result in a delay of appearance of age-appropriate skills. For example, a parent's anxiety over a toddler's growing motoric independence may slow the development of motor skills and the elaboration of exploration. An infant's particular stage of development may influence which issues are most salient and most vulnerable to stress. During an *evaluation* session, stage-specific developmental characteristics also may influence not only the child's ability to demonstrate mastery of certain developmental skills, but also how the infant approaches challenges, including challenges elicited during a developmental assessment. For example, toddlers struggling with emerging independence may react differently to an evaluator's *assessment* tasks than would the younger infant who is focused more establishing social reciprocity and engaging his or her surrounding environment.

Reviewing research over the past decade, Zeanah et al. (54) concluded that there exist four distinct stages of qualitative reorganization during the first 3 years of life. [See also Greenspan (55).] Although their perspective is primarily focused on social-emotional aspects of development and draws from recent research and theory, the stages correspond rather closely to those of earlier developmentalists, especially Piaget and Inhelder (56). Indeed, many of the qualitative changes in cognitive development first proposed by Piaget seem to provide the prerequisites for

qualitative changes in social and emotional functioning now being proposed. The following description of different stages during infancy and toddlerhood illustrate these qualitative changes, as well as the dynamic interaction between maturational processes and social relationships and the interactive nature of development across cognitive, sensorial, social, linguistic, and motoric domains.

Five Qualitative Stages of Infancy and Toddlerhood

The Stage 1 Prenatal Development

Although infants with birth defects or malformations are not routinely brought to child psychiatry as the first referral, child psychiatrists working with young children and their families necessarily consider the child's pregnancy. In instances of developmental delays, careful histories regarding exposures to illness or toxins during pregnancy, rate of maternal weight gain, ease or difficulty of delivery, or immediate postnatal complications are important landmarks for charting the health of the pregnancy. Additionally, and especially relevant to child psychiatry, are parental expectations and wishes for the unborn infant. Does the pregnancy come at an optimal or a stressful time for the parent or parents? Have there been major life events during the pregnancy that the parents now associate with their child's development such as the illness of an elderly parent, a job loss, a sudden move? How do the parents imagine their infant to be (a process sometimes referred to as developing a mental portrait of the baby)? This may include imagined personality or physical characteristics, attributions to the fetal patterns of movement during the day (This is going to be a very active baby—kicks all the time), or perceptions of how the fetus is apparently responding to the parents' likes and dislikes such as to favorite foods or music. Does the parent perceive the pregnancy as a burden and the fetus as complicating unnecessarily the parent's life, or is the pregnancy viewed as a positively life-changing event, transforming the parent's views of self and of life in general? The "psychological background" of a pregnancy is critical information for understanding how that infant fits into the family and the parents' perceptions and expectations for that child, especially when young children are referred for behavioral or early regulatory difficulties. These mental portraits are equally important information in instances when infants are severely compromised medically (57).

The Stage 2 Infant (0 to 2 Months)

During the first couple of months postpartum, infants work primarily toward achieving homeostasis, or the capacity for maintaining physiological equilibrium, in the face of internal and external stimulation. However, they are also surprisingly active and sophisticated learners, capable of cross-modally exploring and perceiving

his or her environment, visually tracking objects as they move through space, habituating to invariant stimuli, discriminating novelty, and even anticipating caregiver actions (58).

The Stage 3 Infant (2 to 7 Months)

The second stage (2 to 7 months) is marked primarily by increased social reciprocity between the infant and caregiver(s). This qualitative change follows increased awareness of the external world (made possibly by greatly enhanced visual abilities) and improved coordination of sensory input and nonreflexive (voluntary) motor output occurring at about 1 month of age. During the second stage, the infant's responsive cooing, repertoire of increasingly differentiated emotional responses, and a proclivity toward direct imitation of others' behaviors starting at about 4 months serve to facilitate reciprocal or contingent social interactions. During the latter half of the second stage (beginning as early as about 4 1/2 months), infants start to show an understanding of *object permanence* (the understanding that objects and people continue to exist even when they are no longer within sight or sound) and a rudimentary understanding of the principles of *cause and effect.* These two epiphanies transform the infant's perception of the world and provide the requisite abilities for all future social-cognitive development. The concept of object permanence allows the infant to create mental representations of objects and others. It is therefore a prerequisite skill for imagining and for visual differentiation between caregivers and strangers. Cause-and-effect reasoning leads to increased intentionality of actions. Both of these newfound cognitive abilities make possible simple interactive games between infants and caregivers, such as peek-a-boo.

The Stage 4 Infant (7 to 18 Months)

At about 7 to 9 months another qualitative shift occurs with profound impacts on reciprocal communication and social preference or familial belonging. At this time infants develop a sense of *intersubjectivity,* the understanding that their thought, feelings, gestures, and sounds can be understood by others. Also, at about this age, most infants begin to demonstrate means–end reasoning leading to goal-directed behavior. They can string together several behaviors (more than one) in order to achieve a final outcome, often the attainment of some desired object. Through intersubjectivity and means–ends reasoning, the infant is able to consider caregivers as objects that can be used to get their needs and wants met. (And the stage 3 infant's now solid grasp of object permanence gives him or her a large inventory of these wants and needs.) Together, intersubjectivity and means–end reasoning lead to the beginning of *communicative gesturing* (e.g., the moment when stretching for an object just out of reach becomes pointing to that object while looking at the caregiver in order to request assistance). In the context of all of these qualitative changes in the

way in which the infant interacts with others, social preferences are established and become increasingly salient. At about 6 to 8 months of age, *separation anxiety* is first observable with most infants, peaking at about 14 to 18 months and declining thereafter (59). Relatedly, *stranger anxiety* appears to begin at about 8 months, peaks at about 24 months, and steadily declines thereafter.

By the second half of stage 3 (starting at about 12 months), several new skills in the cognitive, language and motor domains create profound changes. At about 12 months, infants typically first learn to walk, and this new form of independent locomotion, more so than crawling, heralds increased independence and a broadening world. Cognitively, the infant's reasoning becomes strikingly less rigid and more open to alternative solutions. For example, prior to about 12 months, infants who learn that an object is hidden in a particular place will persist in looking for that object at that same location even after watching someone relocate that object to a different location. This is commonly referred to as the AB error. However, after about 12 months the infant's ability to hold increasingly larger amounts of information and to discard outdated information allows for a fluidity of reasoning such that the AB error diminishes or disappears. Given this increased cognitive capacity and fluidity of reasoning, *trial-and-error problem solving* begins to replace conditioned response learning. Also, from about 12 to 18 months, infants develop rudimentary communicative speech. By 12 months most infants understand the meaning of several words and may have an expressive vocabulary of about five or six words. By the time they reach 18 months of age, infants typically understand the meaning of an amazing number of words, can communicate in one-word sentences, and have doubled their expressive vocabulary to about 10 words. Their melodic, jargoned speech patterns now closely resemble the inflections and turn-taking pauses observed in conversation.

The Stage 5 Infant (18 to 36 Months)

At about 18 months an increased ability to use *symbolic representation* transforms the infant's cognitive and social world. About 12 months earlier, object permanence marked the beginning of the infant's ability to hold in the mind mental representations of objects. The stage 4 infant is now well able to allow symbols to stand for objects, heralding greatly increased language proficiency. The use of words marks a qualitative change in the way infants think about the world and interact with others, and, likely, the reverse is true as well (60). The beginning of this transformation appears to be marked by a move from direct imitation of others to *deferred imitation,* where the behaviors of others are remembered and then practiced later. *Symbolic play* appears as the infant uses a doll to symbolize a baby, and the infant begins to combine words and gestures in order to label objects in his or her world or make needs and wants known to caregivers. By 18 months these skills are becoming solidified, and the infant's interactions with others change dramatically.

Additionally, at about 18 to 24 months, *internal problem solving* begins to replace trial-and-error problem solving, as the infant's ability to mentally hold and manipulate internal representations increases. From 18 to 24 months, toddlers' expressive vocabularies typically increase from about 10 words to about 50 to 75 words. By 30 months, the toddler's expressive vocabulary has increased to nearly 300 words, and by 36 months many toddlers have an expressive vocabulary of 500 to 1,000 words and typically speak in three- to four-word sentences (61).

FORCES THAT MAY COMPROMISE NORMATIVE DEVELOPMENT

A variety of both endogenous and exogenous forces may compromise normal infant and toddler development. These are described briefly below and listed in Table 2.1.1.1.

Regulatory Disturbances

These include disturbances in self-regulatory capacities, such as sleep or eating disturbances, including food refusal, night terrors, repeated waking, or problems in impulse control such as excessively aggressive behavior. Low frustration tolerance is another mark of regulatory difficulties. Self-stimulatory behaviors, such as rocking or head banging, may indicate a variety of social or regulatory difficulties, may be a manifestation of environmental stress, or may signify more profound difficulties in relatedness, as in pervasive developmental disorder.

TABLE 2.1.1.1

FORCES THAT MAY COMPROMISE NORMATIVE DEVELOPMENTAL PROCESSES

1. **Regulatory Disturbances**
   A. Sleep disturbances (frequent waking)
   B. Excessive crying or irritability
   C. Eating difficulties (finicky eating or food refusal)
   D. Low frustration tolerance
   E. Self-stimulatory/unusual movements (rocking, head banging, excessive finger sucking)
2. **Social/environmental Disturbances**
   A. Failure to discriminate caregiver
   B. Apathetic, withdrawn, no expression of affect or interest in social interaction
   C. Excessive negativism
   D. No interest in objects or play
   E. Abuse, neglect, or multiple placements or caregivers
   F. Repeated or prolonged separations from caregivers
3. **Psychophysiological Disturbances**
   A. Nonorganic failure to thrive
   B. Recurrent vomiting or chronic diarrhea
   C. Recurrent dermatitis
   D. Recurrent wheezing

4. **Developmental Delays**
   A. Specific delays (gross motor, language)
   B. General delays or arrested development
5. **Genetic and Metabolic Disorders with Known Neurodevelopmental Sequelae**
   A. Down syndrome
   B. Fragile X syndrome
   C. Inborn errors of metabolism
6. **Exposure to Toxins**
   A. Fetal alcohol syndrome
   B. Lead poisoning
7. **Central Nervous System Damage**
   A. Traumatic brain injuries
   B. Intraventricular hemorrhages
8. **Prematurity and Serious Illnesses Early in Life**

Social/Environmental Disturbances

Disturbances in social development and/or the caregiving environment, including serious and profound problems in differentiating mother or caregiver, such as might be seen in pervasive developmental disorder or infantile autism, and disturbances in predominant mood. Infants who are predominantly withdrawn and apathetic are at great risk for developmental difficulties. In this category are also included environmental conditions such as repeated or prolonged separations or neglect, abuse, and exposure to violence, all of which place infants at risk for social and affective disturbances (30).

Psychophysiological Disturbances

These include, among others, failure to thrive, recurrent vomiting, wheezing, or chronic skin rashes. The younger the child, the more likely the response to an environmental stress will be a global one involving several organ systems (e.g., failure to thrive). Clearly, any one of these problems may have physical causes, but clinicians should be alert to the close connection between physiological and psychological adjustment in young children.

Developmental Delays

Delays in specific areas of development, including motor development and activity, language and communication, awareness of others and degree of relatedness to others (seen often together with language delay), or delays in more than one of these areas. Such delays may be more common among infants with complicated perinatal courses such as those born severely premature or following parental substance abuse and prenatal exposure to alcohol, cocaine, or other drugs. Thus, infants with such histories will more often be referred for assessments early in order to plan for appropriate interventions.

Genetic and Metabolic Disorders with Known Neurodevelopmental Sequelae

Various genetic and metabolic disorders have known neurodevelopmental sequelae. These include, but are not limited to, Down syndrome, fragile X, Prader–Willi, certain sex chromosome anomalies (e.g., Klinefelter syndrome), and poorly managed phenylketonuria (PKU) (62). Although certain developmental and behavioral sequelae are associated with these conditions, the extent can often vary considerably, and developmental assessment can be useful to document its course and better target psychosocial interventions.

Exposure to Toxins

Exposure to environmental toxins, such as the case with fetal alcohol syndrome and lead poisoning, has been associated with both developmental delays and behavioral dysregulation. Though useful in treatment planning, assessments are not able to determine the proportion of the developmental presentation attributable to these potential causal factors.

Central Nervous System Damage

Central nervous system damage (e.g., traumatic brain injuries and intraventricular hemorrhages) can, of course, lead to developmental sequelae, and follow-up with a developmentalist can be invaluable in understanding the level of functional impairment and tracking recovery.

Prematurity and Early Illnesses

Prematurity and other serious medical conditions that may result in hospitalization or other restriction of appropriate stimulation early in a child's life, may lead to altered parent–child interaction and adversely affect development (63).

Extant research suggests that the specific disturbances and conditions listed above are highly interrelated and mediated by the social context of the child (64). For example, failure to thrive may also indicate social (the family and caregiver–child dyadic relationships) and/or environmental disturbances, or general developmental delay may occur with repeated separations or in a withdrawn, apathetic child. A particular developmental profile, such as delayed language skills but age-appropriate motor and problem-solving skills, may occur with different presenting difficulties, and thus it is not possible to specify a characteristic diagnostic developmental pattern for failure to thrive, sleep disturbances, or the other problems listed in the table.

In addition to the above caveats, three general points are important to remember.

First, language and communication skills are particularly vulnerable to biological and environmental stresses. Moreover, problems in communication also affect personal-social development. For most of the problems listed under social/environmental disturbances, the infant will likely show minimally delayed language and personal-social development. Also, any adaptive or motor items that require interaction with the examiner will be affected by disturbances in relatedness, and the child's skills in these areas will appear scattered not necessarily because of motor impairment but because of the necessity for social interaction for administering the item. Second, it is possible for an infant presenting with some of the difficulties outlined in the table to have an age-appropriate developmental profile in terms of what things the child can and cannot do. In this case, the qualitative observations of how the infant approaches the setting are crucial. The qualitative aspects of the child's interactions with the caregiver and the evaluator, motivations, problem-solving processes, and mood state are infinitely more important than a simple inventory of the infant's skills. Third, an infant's or toddler's level of developmental functioning may vary considerably between domains. Infants with psychophysiological disturbances often show such a "scattered" developmental profile. Qualitative observations are again important with this kind of profile, as well as repeated assessments over time in order to gain a better sense of the child's developmental trajectory.

Generally, a comprehensive assessment of a young child provides a description of the child's functional capacities, the relationships among the various domains such as language and socialization, the child's ability to adapt, and the range of coping strategies. For the very young infant, developmental assessments describe neurodevelopmental functioning and individual regulatory capacities. For caregivers, the evaluation provides information about both their child and the potential therapeutic value of the alliance established with the clinician. For the referring clinician, the assessment may provide a more integrated view of the infant's psychological as well as physical status. Finally, infant assessments often serve the purpose of facilitating referrals to appropriate educational or rehabilitative services. In such cases, the useful question is not whether or not the infant is delayed or has problems, but what are the most appropriate services to ameliorate these problems or to compensate for these conditions. In cases such as these, the evaluating clinicians will need to be collaborators themselves with individuals directing intervention and educational services for infants. [Several excellent reviews of the effectiveness of early intervention services for infants are available (64–66).]

SUMMARY

Infant psychiatry is a developing field that brings child psychiatrists into closer work with very young children and their parents. Disorders such as autism have long been

recognized as specific developmental disorders requiring intensive child psychiatric care but more recently, early regulatory disturbances, disruptions in attachments, prematurity, and other biologic disruptions have come into the purview of child psychiatrists. Working with infants and toddlers brings child psychiatrists into close contact with rapidly developing systems and infant psychiatry requires a detailed appreciation of the range of normative as well as abnormal development and an understanding of how different caregiving environments may dramatically alter developmental trajectories, especially in the first years of life. The child psychiatrist with a special interest in infancy and early childhood by virtue of his or her medical training has a special appreciation of the biological aspects of early development. The contemporary infant psychiatrist has available the wealth of data from many infant observational studies, from genetic and neurobiologic perspectives, and from a rich multidisciplinary environment of professionals working with infants, toddlers, and their families that includes developmental psychologists, social workers, pediatricians, geneticists, and developmental neurobiologists. Further, the infant psychiatrist is constantly integrating biology with an understanding of the infant's adult caring environment and assessing the relationship between infant and family as much as the developmental integrity of the infant.

CHAPTER 2.1.2 ■ THE PRESCHOOL CHILD

LAURA STOUT SOSINSKY, WALTER S. GILLIAM, AND LINDA C. MAYES

Between the ages of 2 and 5 years and under average conditions, children's cognitive, social, and emotional worlds are rapidly expanding and changing (1). Their language abilities expand their capacity for imagination and symbolic thinking and for enlarging social relationships. Their changing cognitive capacities expand their ability for problem-solving and learning about the world. They develop the ability to name their own and others' feelings and to relate behavior to emotional states and expressions. During the preschool period of development, children are even more commonly in broader social worlds, such as child care and early childhood education programs, and may also experience the birth of a new sibling. While pediatricians remain the most likely professional to be consulted by parents when they are concerned about their 2- to 5-year-old child's health and development (throughout this chapter, the use of the word "parent" is inclusive of all adults that assume an important and regular role in providing care to the child), a number of other professionals are very likely to be involved in a preschooler's life, including child care and educational professionals. Also, this developmental period marks the beginning of more common referrals to child psychiatrists. These referrals come from teachers, parents, and pediatricians most commonly for behavioral problems, especially excessive aggression with peers or other adults, separation difficulties when faced with school and child care programs, developmental delays, especially of speech and language, and concerns about social delays, especially as these relate to social disabilities such as autism.

Development of behavior and competencies is a process of change over time as a child's characteristics reciprocally transact with the immediate caregiving environment and the broader ecological context, as discussed in the previous chapter on infant and toddler development (2–6; see Chapter 2.1.1). In the preschool years, specific features of these elements that differ from the earlier infancy and toddlerhood period include, for most preschoolers, increasing sophistication and capacity of cognitive, communicative, and social-emotional skills, a longer history of more varied experiences with parents and primary caregivers, and the high likelihood of exposure, often extensive, to nonparental early care and education contexts, perhaps for the first time.

As with infancy and toddlerhood, the diagnostic nosology for specific disorders among preschool children is only beginning to emerge and only a few diagnostic labels, such as autism and the related social disabilities, are commonly used. Furthermore, social-emotional well-being has received lesser emphasis relative to the impact of cognitive and linguistic competencies on later child outcomes. In addition, developmental change in early childhood is rapid, and assessment of

normal and problematic behaviors can be challenging. However, there is a growing body of research evidence that social-emotional and behavioral problems in early childhood are real, not transient, and that occurrence and persistence are associated both with co-occurrence of other problems and with family and parenting difficulties (7). From this and other work, there is general consensus that the understanding of a child's development requires an appreciation of the caregiving contexts which support, protect, and nurture the child during this period of dependence on adults (8).

In this chapter, we review several areas relevant to preschool children's development and those issues about which child psychiatrists may be most often called upon to consult with families and teachers. The basic developmental areas of normative preschool development include (a) robust language learning, including the word-learning explosion and use of language to express emotions and convey more complex or hypothetical information; (b) emerging thinking and learning capacities, including executive functioning skills as well as the young child's emerging ability to reflect on his own and others' mental activities—feelings, dreams, beliefs, and thoughts; (c) emerging peer relationships and the capacity for imaginary play (and imaginary friends); and (d) normative issues regarding separation and individuation. Consideration is given to each of these areas' transactions over time with each other, with caregiving, and with the broader environmental context. Understanding these basic developmental areas is key to a child psychiatrist's ability to consult effectively when parents and teachers bring developmental concerns about a young child.

In terms of specific consultative questions, we cover three areas in brief—fears and apparent anxiety, aggressive behavior, and child psychiatric consultation to preschool settings as examples of the more common reasons for child psychiatric involvement with preschool children. Specific diagnoses including autism, conduct or oppositional difficulties, attentional problems, and assessment for developmental delay are covered elsewhere in this volume.

LANGUAGE

A word-learning language explosion begins at about 18 months and continues through the preschool years, during which children learn on average about nine words per day. Language acquisition is robust, with children learning vocabulary and the fundamentals of linguistic semantics by age 4 or 5, even with very little environmental support (as exemplified by deaf children's early communication even without language input). However, there appears to be a sensitive period for language proficiency. The specific language a child learns and linguistic qualities such as morphology, grammar, phonology, verbal expression of emotions, and conveyance of information about past, present, or hypothetical events are best learned by the preschool period. The difference among children of differing language

proficiency levels on these linguistic qualities is not as much whether or not they can use these linguistic skills, but in the frequency and effectiveness with which they use them in their daily lives. The ease at which these skills can be learned begins to decline at about 6 or 7 years of age (9).

As language proficiency is pivotal for subsequent cognitive and social development, especially school readiness and success, the contributors to development of language proficiency are of great interest. There is evidence that the amount of talk caregivers (usually mothers) direct toward their young children is associated with vocabulary growth and preliteracy skills. The amount and richness of the vocabulary children are exposed to, both child- and other-directed, is also related to language development (10). The genetic contribution of parents is of course important, but so is the family's socioeconomic status, with children of lower income, less-educated parents receiving less quantity and quality of linguistic exposure and demonstrating lower levels of language proficiency (9). Indeed, recent research finds that, by 2 years of age, the disparities between children from higher- and lower-SES families are equivalent to a 6-month gap in both language processing skills and vocabulary knowledge (11).

EMERGING MINDS

Beginning around 2 years of age, young children start to form more stable concepts of the world around them. They begin to think symbolically—to use one object to stand for others. For example, young children use scribbled drawings to represent houses, people, animals—and to tell stories using these scribbled bits.

Moreover, in the preschool period, there begin to be vast individual differences in children's executive functioning—a child's capabilities to self-regulate, sequence, plan, and organize. The development of these executive controls has a global and lasting effect on later competencies, and problems in executive functioning can lead to later school problems. In contrast, there is little individual variation in normally developing preschoolers' disposition toward a positive motivation. Young children are intrinsically motivated to explore, try, and learn. In the preschool period, this intrinsic motivation is related to self-attributions about their abilities that are indiscriminately positive. Typically developing preschoolers often perceive themselves as being the best at everything, and to be getting better and better everyday. This disposition often declines on school entry, which may be related to improved cognitive abilities of self-appraisal and social comparison, but is also likely associated with a greater exposure to peers and the increased judgment and potential for criticism in formal school environments. Early education, whether formal or informal by parents and caregivers, should have as a goal encouragement of a child's natural inclination to explore and learn, not only to foster cognitive skills but also a positive motivation toward learning (9).

The preschool period is also marked by the beginnings of concerted attention to a child's skills and abilities considered basic to school readiness, as well as basic self-care skills. Children acquire skills best when caregivers present them with tasks that are just a bit too difficult to accomplish independently, but are possible with appropriate assistance, or "scaffolding." This highly effective approach to teaching young children requires a certain degree of sensitivity to the child's developmental level, often referred to as the child's "zone of proximal development" (12). In addition to this type of parent–child interaction, parents encourage their child's preliteracy and premath skills with activities such as reading (13), quantitative games, and provision of opportunities such as trips to the library. These activities are most influential when undertaken in warm and nurturing routines. Being read to has the most impact when the child is comfortably and regularly cuddled in a parent's lap for a bedtime story (9).

By the time children are 4 to 5 years old, they have acquired the ability to understand that their thoughts, beliefs, and feelings are their own and that others may feel differently, even believe differently from them. Interpreting the behaviors and words of others as being a part of their feelings and thoughts is a major part of being human and getting along in a social world. This capacity is a remarkable developmental achievement covered broadly under the term *developing theory of mind*—the notion that a part of social development is seeing the world in both physical and nonphysical terms, with the latter being invisible or imagined states of thoughts, feelings, and beliefs. There is a large literature on the emerging theory of mind in young children, especially as a capacity that does not develop fully in autistic children, and several have proposed distinct stages in this developmental progression—from a physical stance (the world is as we see it, and we predict the world based on the laws of nature) to an intentional stance in which we understand and predict the world at the level of mental states—beliefs, feelings, fears, worries. The boy is crying because he misses his grandmother, or the girl is happy because she got the present she was hoping to receive.

Once children begin to see the world through the lens of mental states, their understanding of their own self and others greatly expands. They are capable then, for example, of playful deceit—hiding something in a way that sends another person down the wrong path because they understand that by providing deceptive clues, the other person develops a false belief as to the whereabouts of an object. They become capable of subtle sarcasm, understanding that just by a change in a tone of voice, someone else reads their intent and not just the meaning of their words. However, during the preschool years, these capacities are just emerging and tend to disappear at moments of fatigue or stress. Thus, a clinician working with a 4-year-old who has been remarkably clear about his feelings and the feelings of others may be very surprised when a usually competent boy melts in disappointment or anger because he was sure his mother knew exactly what he was thinking about for his birthday.

Further, under stress or unusually severe trauma and neglect, it is very difficult for children to fully develop or allow themselves to imagine the intentions of others who may have been hurtful or neglectful and thus, clinicians working with severely disadvantaged populations may see a delay in the appearance of these very important social perspective-taking capacities. Thus, in addition to understanding where their patients are in basic developmental domains such as cognition, language, fine and gross motor, child psychiatrists working with young children need also to evaluate where their preschool patient is in his/her capacity to think about his own feelings and beliefs as well as those of others. This is most evident in their play (see next section) and less often through direct questions of "How do you feel?" or "What do you think?" though they may answer such questions indirectly about characters in a story or in a play sequence of their own.

PLAY

Play, broadly defined, covers many activities. One is the rough and tumble play of children running, jumping, chasing, and wrestling with one another. This form is universal across most cultures, and even across different species. Play also includes verbal forms that are uniquely human, in which children play with sounds and words, even inventing their own language and rhymes—and it is this capacity that is most central to a child psychiatrist's ability to communicate with younger children through the special language of play. Manipulating and exploring toys and other objects is a form of play that gives young children a chance to learn by looking, feeling, tasting, listening—a form of trial and error, hands-on learning.

Pretend Play

Children's pretend play varies remarkably in quality, content, intensity, and engagement with other children and adults. In part, their developmental maturity defines the type of play they are capable of creating. Pretend play begins around age 2, or just before children are able to let a real object stand for another or for something imaginary. When a toddler begins to brush a doll's hair, this is the very beginning of her ability to pretend. She is using a toy (a doll) with a real object (a brush) to represent a real action. When she starts to feed the doll with a spoon, making lip-smacking noises and blowing on the spoon to cool the soup, she has gone one step further. She is "representing" imaginary food. And when she offers that food to another doll or an adult, the full ability to pretend—to represent her mental world through play—is in evidence.

The ability to pretend requires the ability to symbolize—to let one thing stand for another, just as a picture of a car stands for a real car. The ability to create symbols or representations is part of entering a more complex and layered world of social

communication. There are several different levels or stages in learning to use symbols. In the earliest, a baby picks up a spoon and touches it to the edge of a bowl. She thus shows she understands this object's use—what actions a spoon is associated with, even when she is not using it for that action. A variant on this later stage is when a child "eats" from an empty spoon and looks with a smile to her father as she nibbles. Similarly, a toddler can act out sleep, closing his eyes for a few seconds before looking to see if a parent is watching. When a preschooler pretends to feed a doll and read it a story, he shows he is capable of a more complicated level of pretense. And when children begin turning one representation into another, such as having a cup be a hat, their pretend abilities are at an even more sophisticated level. That opens up more avenues for expression.

Peer Play

Play with peers and establishing relationships with other children is "one of the major developmental tasks of early childhood" (9). Both the type and the complexity of play have been studied, specifically in regard to prosocial play, engaged behavior, and emotional expression during play. A child's acceptance among peers also begins to vary in the preschool years, although peer like- or dislike-nominations are very unstable at this time. A striking increase in social skills occurs in the preschool years, and peer play increasingly involves pretense (described further below) and expanded numbers of children.

Very young children under 3 years of age often play alone with a toy or other object. They may roll a truck around and make authentic truck sounds. But they make no special effort to invite others to join their play. In "parallel play," which is also characteristic of children 3 years of age and younger, two or more children play by themselves but close to each other. They may even use similar toys, such as a bucket and sand, but they are not playing with one another. They are simply in close proximity.

Children 3 to 4 years old begin to engage one another. They share toys, pass them back and forth, even talk about the same activity and follow one another. Their play is still not completely cooperative, however. If preschoolers have no real companion nearby, they may engage an imaginary friend as a playmate. When children are around 4 years and older, they begin to engage one another in games in which they must share a goal and a story. They assign roles, direct action, even carry stories and games from day to day.

Peer play is influenced by caregivers. Secure attachment relationships have been associated with higher levels of social competence, greater preschool popularity, and more positive friendships (14,15). In addition, parents' role in helping children play well with others and provision of peer play opportunities, monitoring of peer interactions, modeling and coaching acceptable behaviors, and discouraging

unacceptable behaviors are all associated with more positive peer relationships (9).

A child's temperament is also related to his or her peer interactions. Inhibition hinders children's peer interactions, although excessive exuberance can also cause difficulties. More importantly, the child's ability to regulate his or her individual temperament is associated with peer-interaction skills. A child's competencies at sustained attention, controlled expression of negative emotion, and ability to inhibit certain actions are more related to positive peer interactions and relationships than is underlying temperament as such (9).

Clinical Use of Play

One of the important skills for a child psychiatrist working with younger children is learning how to use play therapeutically and as a means of communicating with young children about what is uppermost in their minds. Often children who have been neglected or otherwise stressed and traumatized are unable to use play adaptively and unable to engage in imaginative fantasy play. If we consider play as a special language for communication with younger children, it is appropriate to work with a young child to enhance their ability to play as a means of expression of anxieties and worries (though play should never be taken as a veridical account of children's past experiences). To use play therapeutically requires different techniques from simply joining in with children's play. For one, the child psychiatrist is always trying to understand what a child may be conveying through his or her play—why this burst of anger in the animals surrounding the house? why the lonely child whose cries are never heard? At the same time, direct interpretation of play, that is, taking the imaginary action and translating it into questions about the child's own experiences, is not always effective inasmuch as young children are not always able or aware of using play characters and themes to tell stories directly reflective of their own experiences. Their play may reflect what is concerning to them—how to handle being angry or feeling lonely—but this is not the same as interpreting, for example, the lonely crying child in the play as being a direct statement of an experience the patient must have had. Thus, while there is a considerable literature on this issue, child psychiatrists using play as a therapeutic technique may be more effective by staying "within the play" and, for example, introducing another character who also feels very lonely and lost and does not know what to do or a character who comes along to help. Either way, the therapist is working within the child's story to try to help the child expand his expression of his feelings and his beliefs in a way that helps the therapist better understand the patient.

Many preschool children—up to half, according to some surveys—create imaginary companions and insist on their reality. For children under 5, the boundary between fact and fantasy is often more fluid. But if pressed, most preschoolers will agree that their friends are not really visible, not really hungry, not really sleeping

beside them. Imaginary friends seem to serve a number of normative purposes including companionship. Indeed, the forms that imaginary friends take often reflect children's concerns and anxieties, just as their games do. An imaginary friend can offer a child psychological protection from her worries by taking on magical powers, or even by succumbing to dangers in the child's place. Child psychiatrists are often faced with distinguishing between the normative use of an imaginary friend and a young child's more than expected difficulty in distinguishing real from pretend. With younger children, this distinction may be especially difficult and requires seeing the child in more than one setting and over time.

SEPARATION

Typically developing preschool-aged children are struggling between independence and dependence, to be both "grown up" and at the same time able to turn to their parents. Especially around separations and transitions, preschoolers are often unpredictable and emotionally labile. They can effortlessly separate for child care one day and the next tearfully cling to their parents. An outside stress, such as the birth of a new baby, may make separation more difficult. Many preschoolers have had some successful experiences with separations, such as going to child care or staying at home with a babysitter. Each separation successfully weathered enhances the preschooler's ability to withstand the next.

Preschoolers often struggle to deal with separations because their repertoire of coping abilities is still developing. Older children can call on their increased cognitive abilities and a repertoire of past experiences, but preschool children do not always have the cognitive abilities to reassure themselves that each separation will work out. This is why it is very common for a preschool child to question her parents repeatedly, even about daily experiences like child care, and ask to be reassured about when parents will return, where they will be during the day, and who will pick them up. Parents often feel confused, frustrated, and guilty hearing these questions repeated, but preschool children ask because they are using their newfound language skills to deal with uncertainty.

Preschool children's emerging symbolic capacities also help them cope with separations—a stuffed animal or other favorite toy, a picture, or even something belonging to their parent can stand for a person they miss. Preschoolers' use of symbolic possessions also shows their newfound capacity for "object constancy," the knowledge that something can be out of sight but nonetheless continue to exist. Preschool children are just beginning to grasp this idea as it pertains to people. They are starting to create mental images of their absent parents and to wonder what people are doing when they are not with them. Nearly every young child worries about being left alone or separated from his parents. This is true no matter how thoughtful or careful parents have been or even if they have not been separated from

their preschoolers. Children especially need their parents close when they are afraid, feeling sick, or going through important changes, such as moving or starting a new school.

Parents are often surprised at how hard it is for a preschooler to say goodbye to a favorite teacher at the end of the year, or accept a new teacher the following year. Children this age also mourn the loss of a regular babysitter or nanny, and do not easily replace that person with someone new. Preschoolers need help in mastering the experience of parting with people outside the family. They need to be reassured that their caregiver did not leave because of them. Visits with an old nanny or teacher after the farewell are helpful, as are pictures, letters, and phone calls. Sometimes parents think continued contact will make it harder for their children to get used to a new teacher or nanny, and feel that it is best for the child to experience a "clean break" with their previous teacher or nanny. This approach, however, rarely helps preschoolers. Even years later, children may mention an early teacher or babysitter parents had long forgotten. They return time and time again to rework the separation and think about what that person meant in their lives.

An especially difficult separation for young children may be during parental separation and divorce (16). How does the nearly inevitable conflict between parents that accompanies divorce affects a young child still concerned about consistency and object constancy? What is the impact of parental loss versus shared custody? Goldstein et al. (17) emphasized the critical roles of clinical expertise and opinion in serving the best interests of young children in custody disputes, and it is an increasingly common consultation for child psychiatrists to be asked either by a court or by parents to consult about how best to help a young child in the instance of parental conflict and divorce.

The principle of continuity of care, so often stressed for young children as essential for their ability to deal with separation, comes into practical application in two major decisions during divorce—custody and visitation. By and large, for preschool children, single-parent—rather than two-parent—custody remains the most common decision of courts but joint custody is increasing as fathers want to be more involved in their children's lives and more mothers face the difficulties of working full time and raising a family. While there is no firm empirical evidence to support either alternative, experiential case reports do suggest that younger children do better when parents are able to minimize the degree of discord and conflict and/or avoid catching the child in the middle of their disputes. Similarly, there are few to no systematic data about appropriate visitation models but it is clear that consistency, structure, and predictability are keys, especially as preschoolers are highly dependent on routines and dependable structure. Child psychiatrists specializing in work with younger children may be involved not only in consultation to the court but also in ongoing consultation to one or both parents for how best to care for their child and how both parents, if they so desire or if appropriate, may have a role in their

child's life.

FEARS AND ANXIETY

Fears, worries, and anxiety are often more evident in children's second and third years, even as separation and stranger anxiety wane. This fearfulness and caution is normative. It keeps a very young, very small child from straying too far. While it may sound paradoxical, children who are well cared for are more able to experience normal fear and worry and thus to run back to their parents for comfort and reassurance. Children who have been neglected and abused are more often heedless of danger. They cannot easily recognize normal feelings of fear and worry as protective signals (18).

Despite their energy and enormous interest in the world, 2- and 3-year-old children are still quite dependent on adults and are still often preoccupied, even in the most optimal of situations, with the constancy of the important people in their lives. They feel apprehensive not just about new things they encounter but also about what appears in their thoughts and fantasies. They may feel particularly uneasy at bedtime when they are about to be left alone. Preschool children soothe their worries through constancy and routines. Indeed, such rituals are the essence of this age. If a child can keep things around her unchanging and predictable, the world seems a little less uncertain and daunting. For the child psychiatrist asked to evaluate a young child who becomes inconsolable with the slightest change in routine, the question is how normative versus how rigid such routines are, what purpose they serve, and how they fit in the child's daily routine.

Fears and worries also become more evident in the preschool years because, as discussed earlier, this is when the capacities for imagination greatly expand—and usually what young children imagine is far more frightening than their actual experiences. Their bad dreams seem real, and for them there is only a thin line between scary thoughts and actual events. Playing about monsters, they may suddenly become quite scared when they hear a door open elsewhere in the house. Two- and three-year-olds are certain that just by thinking about scary things, they can sometimes make them happen. They are sure that everyone knows about their occasionally angry thoughts, and that such anger can actually harm others. Young children thus feel simultaneously powerful and helpless, at the center of their world and insignificant. They have the power to make things happen and, at the same time, are so small in the face of the bad things they can imagine in the world. All this is cause for normal anxieties but once again, often poses a diagnostic challenge for a child psychiatrist who must distinguish between what is usual for age and what has gone beyond the bounds of normative to be constrictive and maladaptive.

Unlike older children and adults, preschoolers cannot always talk explicitly about their worries or try to avoid the thoughts or situations that frighten them. Often,

therefore, they show their fears in paradoxical ways. Afraid of the vacuum cleaner, they may actively avoid it, or they may constantly try to explore and master it. Fearing the dark, they may play with turning the lights on and off or be frantic whenever they are left alone in their beds at night. They may become ever more insistent on certain rituals. Some preschoolers meet any change in their routine with irritability. Young children going through a particularly worrisome time may have routines about food, clothing, bathing, and going to school. These routines are soothingly predictable whenever the child feels uncertain and confused. At the same time, insistence on sameness is a characteristic of a number of early developmental disorders and the consulting child psychiatrist faces, as with other issues raised in this chapter, the dilemma of sorting normative from maladaptive.

Often young children show their worry and fear in ways that seem unexpected, such that the more anxious they are, the more active and uncontrollable they become. Often they are so excited that they cannot heed their parents' or teachers' efforts to help them. Some adults might interpret this behavior as willful or oppositional, but it often reflects a state of such internal overstimulation and anxiety that the child simply cannot control himself. For some children, worries and fears are not simply responses to developmental pressures or the stresses of ordinary living. Rather, their strong, often overwhelming feelings grow out of proportion to their experiences. Anxieties interfere with their lives at school and home, with their friendships, and with their pleasure in play. This increase in worry can be a part of a stressful life event, such as the birth of a new sibling, an illness, or a death in the family.

AGGRESSION

Aggression is a complex set of behaviors, especially in preschool children that reflects a balance between response to frustration versus assertiveness and individuation. Aggressive behavior is one of the more common reasons for child psychiatry consultation, especially in the context of a young child's placement in a child care or educational setting. Furthermore, out of control, aggressive behavior may be one of the most common difficulties between young children and their parents that prompt families to seek mental health consultation. Thus, understanding aggression as both a normative developmental requirement and a possible symptom is the key to effective child psychiatric consultation.

Aggressive behavior in young children has many roots and serves some important social roles. Furthermore, adults have considerable influence over how children view and express their aggressive thoughts. While some variables in a child's aggression, such as her basic tolerance for frustration, may depend in part on genetic endowment and/or early experience, many others are shaped by what he or she learns from her experiences with parents and teachers.

At the very least, aggressive behaviors always express some needs and feelings of

the child. Also, children who enter their second year of life with few words sometimes may exhibit greater levels of physical aggression than their more verbose peers because they have no other means to express their needs and frustrations. Some children rarely, if ever, express themselves through aggressive behaviors, while others find aggressive behaviors a ready and comfortable way of communicating. Reliance on aggressive behaviors to meet needs can be modeled by parents, other adults, peers, and siblings, and screen media (television, videos, movies, computer games).

For very young children, aggressive behavior is also a way of expressing independence, as in “Mine!” “Me do!” and “Go away!” These firm statements may be unpleasant, even hurtful, to another person or anger an adult. Toddlers’ temper tantrums, while surely tempestuous and irritating for parents, are statements of frustration. These young children often feel small, dependent, and powerless, but as they grow, their need for independence grows too. Thus, developmentally, temper tantrums begin as children start to experiment with separation from their parents. The more they move away from the emotionally secure base of the parent, the more dependent and little they may feel, and the more vulnerable to frustration and tantrums they may become.

Aggressive feelings and thoughts, not necessarily expressed in behavior, are also a central part of young children’s fantasy lives. They are small and dependent upon a much larger, stronger adult world. They struggle for independence—to be “grown up.” Pretending to be very powerful, even scary and aggressive, is one way to play with getting bigger. In preschool children, aggressive behaviors have different intents, causes, and outcomes.

In trying to figure out why a child is biting or hitting, it is important for the child psychiatrist to ask where she directs her violence: toward other people or only toward inanimate objects? In other words, does she kick and break toys or kick and hurt her classmates, siblings, and parents? What typically starts the aggressive behavior? Is she frustrated by wanting a toy she cannot have, or by wishing to be hugged by a very busy parent or teacher? Is she very tired or very excited—at the end of the day or just after a puppeteer has visited the child care center? Is she reacting to another child’s teasing about her hair, how she fell on the playground, or how she cried when her father left? Did another child hit or push her? It is also wise to consider the apparent intent of a child’s aggressive behavior. Is it a means to an end—to get the desired toy or make a place on the teacher’s lap? Is it to create a personal space—a kind of “don’t tread on me” signal? Does the goal seem to injure or destroy, or is it really to gain another’s attention, to win in a game, or get the best seat in circle time? No child acts aggressively in the same way for the same reasons in every situation. By identifying what a child really wants, her caregivers can tell her not to push or hit while also showing her a better way to achieve her aim, thus reducing her frustration and need to act out.

When evaluating a child's aggression, it is also important to consider how it might be linked to his fears and worries. Such behavior may be a way for him to express how he is really worried deep down without acting fearful. Not all aggressive feelings in children reflect deeper fears and anxiety, but when they do, it is very important for parents and teachers to be made aware of these fears and worries. For most young children, physically aggressive behavior—hitting, biting, pushing, kicking—begins to subside by their third, or at the latest their fourth, birthdays. On the other hand, verbal aggression—shouting, yelling, name-calling—increases between the ages of 2 and 4 years as children gain more language skills. Most often, all kinds of hostile behaviors, verbal and physical, diminish in frequency by 5 or 6 years of age when children enter first and second grade. Younger children are most aggressive around asserting their physical needs and wants. Older children, in contrast, focus their aggression on social situations and needs. Indeed, as children get older, their aggression is more often related to a perceived hurt or slight; they want to pay back an insult to their self-esteem which they perceive from a particular person. Thus, paradoxically, as children get older, they are far less aggressive, but when they are, their actions may be more often intended to harm another person.

Although significant behavior problems during the early years are often stable and predictive of later behavioral difficulties (7), it is not guaranteed that an aggressive preschooler will grow into an aggressive school-age child. Despite parents' and teachers' concerns, the hitting, kicking, biting 3-year old is not guaranteed to become an aggressive school-age child. What matters most is how adults understand and meet aggressive behavior in younger children. By finding methods for young children to strive for mastery, self-assertion, and self-protection, adults support these important developmental tasks without encouraging hostile or violent behavior. Aggression met with aggression is far more likely to convey the message that people can express frustration and anger only through shouting, name-calling, or physical action. Aggression met with an effort to understand what a young child is trying to communicate shows that when people feel frustrated and angry, they can think about how to express those feelings in ways other people understand.

CHILD PSYCHIATRIC CONSULTATION IN PRESCHOOL SETTINGS

There are more preschoolers enrolled in early education and child care programs than ever before (19,20). The recent increase in the number of preschoolers enrolled in formal care outside means that a greater number of young children are coming into contact with potential referral agents (preschool teachers, child care providers), which translates into more psychiatric referrals at lower ages than ever. Rather than simply waiting for these young children and their families to present at the child psychiatrist's office, many child psychiatrists and clinicians of other disciplines have

sought to address the referral issues in the child care or preschool setting (21,22).

There are many advantages to providing child psychiatric services as part of a consultative service to early care and education programs (23). Consultative delivery models afford the clinician an opportunity to observe the patient in a natural setting (e.g., the child care program), observe interactions with often several peers, obtain information about the child's functioning from other adults in addition to the parents, and enlist the assistance of many adults in supporting treatment recommendations. Additionally, children often behave very differently at home versus in their child care programs, where the degree of structure and behavioral expectations may vary considerably. The opportunity to observe the child across these different settings is often invaluable as a way of better understanding potential environmental triggers for the behavioral concerns and understanding the child's capacity to modulate her behavior to match different environmental contexts.

Mental health consultation in early education programs can take many forms. Consultation can be focused solely on classroom-specific reduction of particular behaviors that the teacher finds difficult to manage (peer aggression, tantruming, running out of the classroom), or it can be more global in focus, such as using the classroom experiences to create opportunities for the child to develop competencies that can lead to increased self-efficacy. Sometimes the consultation is focused specifically on the child, but often the consultation may include systemic assistance to the teaching staff regarding how to improve the overall mental health climate in the classroom, facilitating teachers' understanding of children's behaviors and teacher behavior management skills, creating a more efficient and effective system of screening and identifying children in need of assistance, and sometimes even addressing mental health needs in the teaching staff.

Attention paid to the overall functioning of preschool and child care classroom (from the physical setting to interactions between teachers and children) can provide clues to understanding the child's behavior and how best to intervene. When a child and family presents in a psychiatric office, it is essential to understand the effect of familial psychopathology on the young child (24). Similarly, the mental health of preschool teachers, who sometimes spend as many or more waking hours with a preschooler than do his parents, can impact child–adult interactions and contribute to emotional and behavioral difficulties. For example, child care provider depression has been associated with child care that is less sensitive, more detached from the children, and (when not detached) more intrusive or negative (25). Also, child care teachers who report elevated levels of depression or job stress, or depressed levels of job satisfaction, are more likely to report having expelled a preschooler from their classroom in the past year (26). Of course, low wages and relatively high levels of job turnover in the child care workforce (27) may contribute significantly to teacher burnout. Unfortunately, mental health consultation in child care settings may often ignore adult functioning.

SUMMARY

Between 2 and 5 years of age is a time of very rapid development, especially in social and cognitive skills that expand the world for preschool children. They gradually acquire the ability to think in terms of mental states such as feelings and beliefs, to understand others' intentionality, and to play symbolically and imaginatively. Increasingly, they are venturing further from the home, forming relationships with peers and nonfamilial adults in child care and early education settings. Child psychiatrists working with children of this age are often faced with distinguishing normative heightened anxiety, preference for routines, and aggression from presentations in which these same characteristics are maladaptive and in need of intervention. Hence, this developmental period especially calls for a thorough understanding of normal as well as abnormal development. Further, as with infancy, this period of development also brings child psychiatrists in close collaboration and consultation with pediatricians and early childhood education settings.

CHAPTER 2.1.3 ■ DEVELOPMENT OF SCHOOL-AGE CHILDREN

LEE COMBRINCK-GRAHAM AND GERALDINE S. FOX

FOREWORD TO THE FIFTH EDITION

In the 25 years since this chapter was originally drafted, there have been many changes that affect the way we view children, their development, and their health and mental health. This chapter in its current version still follows the lines of development outlined by our venerable ancestors, most significantly Erik Erikson and Jean Piaget. Erikson's eight stages of man, elaborated in Childhood and Society, not only offered a developmental template, but also located an individual child's development squarely in the social context in which the child was developing. Jean Piaget studied the evolution of thinking, and offered the sequence that seems to be a foundation for cognitive development. Other important contributions to our understanding of development either elaborate these two compatible lines or have since proven to be less helpful in understanding the process. However, there have been some significant shifts in viewpoint that may have affected children's progress through this period.

The recent developments we observe that have a profound effect on how children grow, learn, and develop means and strategies for advancing and solving intellectual, social, and emotional problems include the following: (1) An increased focus on psychopathology or learning differences that are seen as "disabilities," and (2) A focus, in school, on achievement measured by standardized tests.

Briefly, how do these changes in focus and understanding affect our view of school-aged children's development, or, indeed, their development itself? (1) Focus on "disability" distracts from looking at how children learn, cope, and problem-solve, and most importantly distracts from the fundamental drive for learning, curiosity. (2) Measuring achievement of children as representing the success of their teachers, schools, and school systems focuses their learning on taking tests and what is needed to pass a test. What is lost in this process for many children is the excitement of discovery. Further, it seems likely that the greater incidence of or recognition of "bullying" is associated with how kids perform in the eyes of other kids, how those who don't perform well may try to compensate by being bullies, and how those who focus on performing well may somehow be socially marginalized. Furthermore, this focus on individuals passing tests makes it difficult to have the kind of learning community that we describe as an essential part of the school-aged child's social and intellectual learning experience. More and more we see schools focusing on individual children and less on holding the peer group accountable for each child's participation and learning.

Considering the effects of the changes in these two areas offers reminders of the importance of social context to development in a way that we cannot ignore. It is not feasible to look at individual children behaving, learning, feeling, and thinking without also examining the contexts in which they do that. We said so in the original chapter, and as we look at the changes summarized above, we are even more struck by this fact.

Research is ongoing regarding the effects of these developments. We write about them to encourage the readers of this chapter to take what is presented as a basic direction of development and the essential accomplishments of development in this period, but to constantly question how our child patients are affected by current trends in the way children are viewed and treated. And how are we professionals affected by these changes as we identify strengths and liabilities in our work toward strengthening the children we see?

INTRODUCTION

The middle years of childhood, spanning the age from when a child enters primary school through the onset of adolescence (ages approximately 5 to 12 in Western cultures), are also referred to as "the school-age period" because of the critical importance of school in development in our society. Many classical theorists have classified this time as the period when a child enters society and begins to establish the basis for becoming a contributing member of his/her community.

Historically, Sigmund Freud, and other drive theorists, described middle childhood as a sexually dormant interlude between the mastery of Oedipal strivings with establishment of the superego, and the pubertal reawakening of sexual desire in a true genital phase. It has since been established that latency is a myth. Erik Erikson provided a more enduring characterization of this period when he described the critical psychological issue: "Industry versus Inferiority" (1). In formal schooling a child is attempting to master the basics of the industry of our society, to build on academic abilities. Failure to progress in school and in the peer context can establish a sense of inferiority, rather than support the momentum of a drive for competence. Neo-Freudians (Sullivan, Horney, Thompson) added an emphasis on social context as the critical shaping force on how this developmental period is negotiated. Harry Stack Sullivan, for example, observed that this "juvenile era" provides the first opportunity for society to "correct" the influence of the family.

Freud, Erikson, and Sullivan defined the important work of this period. Research into the details of cognitive, emotional, and social development confirm that civilization and being-in-society are the essentials of development in the school-age period. Thus, thinking about the child's psychological well-being must extend beyond the child to include not only the family but also the social, economic, and political contexts that define its functioning. Vygotsky's concept of "mind in society" and

Bateson's "ecology of mind" point to the dynamic exchange of experience, accomplishment, and social response and effectiveness. In addition, ecologic theories such as Bronfenbrenner's (2) place development within a range of nested contexts: family as primary, school-as-work as connected and central, as well as larger cultural and societal contexts. Newer work has focused on the interplay basic developmental and contextual processes and links to policy and advocacy for children and teenagers (3).

The best way to emphasize the remarkable growth that occurs during middle childhood is to contrast the skills of children when they enter and exit grade school (Table 2.1.3.1).

Table 2.1.3.1 describes what can be seen in normal average children in the United States, whether they come from poor, inner city neighborhoods, rural settings, or more privileged and educated family backgrounds. Children may be more advanced if they have been provided with educationally stimulating experiences. Children who do not perform at the levels indicated in the table require closer examination to determine whether "delays" are due to disabilities, emotional factors, or contextual factors.

Abundant information supports a rich understanding of how the innate physical, cognitive, psychosexual, and moral maturation of children between the ages of 5 and 12 is meshed with the children's increasing presence in societies outside of the family: the school, the neighborhood, and the extended "family" of the family's community. Without the interaction of child in these societies in such a way that the child's presence and role is identified, confirmed, and appreciated, it is likely that the child will experience what Erikson saw as a developmental failure of this period, inferiority, and all of its consequences.

In this chapter, we will review current information about how children advance from preschool to preadolescence, examining the areas of central nervous system maturation, emotion, gender differences, moral development, social development, and cognition. These areas must be understood in the contexts of the child's internal life, and in relation to family, peers, and school. We will focus greater attention on issues of schooling because, since school-aged children spend most of their waking lives in school, the school environment is vital to every aspect of the child's development, including how the child views the family, how the family views itself in relation to the child, and ultimately how the child views himself.

MATURATION OF THE CENTRAL NERVOUS SYSTEM

The brain undergoes a period of rapid growth through age 2, then develops at a much slower rate until puberty. At birth the brain is estimated to be about 10% of adult volume. It grows to 90% of adult volume by age 5 and completes its growth slowly over the next 9 years. What is more significant than actual volume, however, is the

modification of anatomical structures and myelinization, which is almost completed around the age of 7 (4). Synaptic pruning in the prefrontal cortex (the area affecting social judgment) continues as an ongoing process through adolescence (A).

MRI studies of school-aged children's brains have confirmed these observations. By the age of 7 the child's brain is about the size of the adult brain. Boys' brains are about 10% larger than girls' and this total volume difference persists into adulthood (5,6). Differences, too, are found in the basal ganglia, where the globus pallidus is larger in boys, while the caudate is larger in girls. Boys show a relatively greater increase in size of the amygdala, while girls have more growth of the hippocampus. These relative differences are consistent with findings of androgen receptors in the amygdala and of estrogen receptors in the hippocampus. There are also findings of greater lateral ventricular expansion in boys (4). Caveness et al. (7) found that subcortical gray structures are at adult volume in girls and are greater than their adult volumes in males, while the volume of central white matter is smaller in the female brain. As the frontal lobes develop, children become increasingly able to cognitively inhibit—that is, to focus their attention and refrain from being distracted by irrelevant stimuli (8) (B).

Some data on neurotransmitter development may further sharpen our view of the intrinsic maturational schedule of the child and elucidate the emergence of the abilities of school-age children. Noradrenergic systems develop early and exert early influence on the formation of the cortex. In contrast, dopaminergic systems (associated with attention regulation) and serotoninergic systems (associated with mood and aggression) have a more gradual effect on crucial connections between brainstem nuclei and cortical structures. Cholinergic systems, associated with memory and higher cortical functions, develop relatively late (9).

These refinements in brain structure and function result in the maturation of higher cortical functions, correlating with improved abilities in motor coordination, increased attention and focus, increased self-regulation, and expanded consideration for others (C). The speed of information processing increases significantly between 6 and 12 years of age, which parallels synaptic pruning and myelination (10). For example, tasks of writing, organizing work on a page, coordinating sounds with visual cues (e.g., deciphering words and spelling phonetically) require control in ear and eye–hand coordination. First graders who write letters or words backward, or who write their names with the correct letters but in a different order, are not necessarily showing signs of learning disability. Rather, they have not yet developed mastery of the conventions involving direction and order that are necessary to read and write and perform arithmetic functions. It is normal and expectable to not fully master these conventions until second grade.

TABLE 2.1.3.1

CHARACTERISTICS OF THE SCHOOL-AGED CHILD

Motor	Child entering first grade (5–6 years old)	Completing fifth grade (10–11 years old)
	Hop, skip, jump, throw, catch, kick a ball Reasonable balance, able to stand still and hold arms steady; stands on one foot, left and right General sense of left and right, not always consistent Able to do rapid alternating movements Mild synkinesis on fine finger movements	Hop, skip, jump, throw, catch, and kick a ball with ease. Elaborates: e.g., dance steps; throw behind back or trick the receiver. Balance is good; tandem walking with ease. Accurate distinction of left and right. No synkinesis
Writing and drawing	Able to name and copy circle, square, triangle, and cross easily. Some copy diamond and asterisk. Five-pointed star is possible, if child has been exposed to this in kindergarten Draws person with body, arms, and legs. Can put detailed features, but often leaves them out. Can draw house and tree, as well.	Circle, square, triangle, diamond, asterisk, five-pointed star. Cube can be accomplished, but often only after shown how to draw it. Draws more detailed person with hands, feet, action figures. Girls with more decorative detail. Boys with more action detail.
Stories	About drawings, persons are largely self-referential. Even if a figure has a different name, the life circumstances are usually identical to the child's.	May draw someone who is not self and can have a story about another, even made-up family. Creates complex plots, using well-developed descriptive language.
Fund of knowledge (depends on exposure)	Recites alphabet; counts beyond 20, writes name, first and last. Recognizes printed letters and numbers (not cursive). Writes most letters and numbers. May have some reversals.	Reads aloud and to self with comprehension; performs double-digit addition and subtraction in head; multiplies, divides, and does fractions on paper; knows details about historical figures, geography, natural phenomena, body systems.
Cognitive	Egocentric; idiosyncratic definitions of "scientific" observations. centration, defining by only one dimension; beginning concrete operations: conservation and classification	Conservation of number, weight and volume; flexibility of operational skills, including reversibility
Moral	Defines right and wrong in terms of punishment and pain, or other personal and idiosyncratic rationales. Interested in how the world works, including life and death, religion; uses magical thinking.	Defines right and wrong through internal principles Has empathy and can weigh issues from another's position.
Social	Enjoys the company of other children. Names several friends. Interactional play with rules, often externally determined. Creative play is imitative. Peers judged by whether they are nice to child. Games of individual prowess. May play on team, but cooperates based on rules rather than complex	Likely to have a best friend and a close circle of friends. Activities with peers are increasingly independent of parental supervision Able to create games and make up rules; consideration for others, particularly with girls. Increasing self-reliance and responsibility Peers judged by their qualities. Teamwork

	strategizing.	
Self-view	Dependent on others' descriptions	Dependent on view of success, competence, and evaluation by internal standards, as well as comparison with peers and social pressures. Selects from multiple available models to define standard for "cool" for self and select friends
Sex	Interested in sexual differences; pleasure from touching oneself; generally, play with same-sex friends but comfortable with organized co-ed activities	Secondary sexual changes from Tanner stages I–V, girls usually 2 years ahead of boys. Prefers same sex friends. Some awkwardness about growth (slouching, embarrassment about breast development and foot size). Wide range of pubertal onset in peer group may create challenges to individual self-esteem. Some admiration of individual members of the opposite sex versus thinking others are "yucky." Interest expressed through teasing, messages sent through others.
Family	Identification with parents or siblings, primarily same-sex Participates in family rituals and routines around meals and bedtimes	Compare parents with other adults, including teachers and other children's parents. More independent of family rituals and routines More responsibility for household tasks, own self-care, and homework

MAJOR LINES OF DEVELOPMENT

Psychosexual Development

According to psychoanalytic theory, sexual development is biphasic, with a "latent" period during the school-age years. Freud believed that latency was a distinguishing feature of humans over animals, and hoped to discover anatomical evidence of this through then-promising studies of changes in the interstitial portions of the "sex glands" (11). However, contemporary studies of sex hormones do not support the biphasic theory. Infants have relatively high but varying proportions of sex hormones in cord blood. The levels of sex hormones fall after birth and begin to rise, due to endogenous production, during the school-age period (ages 7 to 8 in girls, and about 2 years later in boys). Sex hormones begin a gradual upsurge around age 8, continuing through the pubertal peak. Children engage in some sexual play with self and others. Some have postulated that school-age children's greater sexual awareness may be reflected in their expressed feelings of disgust and shame and the strong sense of modesty that develops during the school years. Others have reported that sex play among school children is a natural extension of that of preschoolers (12). Infants and toddlers masturbate; preschoolers also engage in mutual exploration.

Children often enter middle childhood with a few good friends of the opposite sex. Around age 8, however, the same-sex groupings become polarized, with the

opposite sex having developing "cooties" and being generally avoided or teased (D). Moving toward preadolescence, however, the "yuckiness" of the opposite sex gradually gives way to admiring certain individuals from a distance (E). Older school-age girls' attraction to movie stars and rock idols serves a group interactional function, as well as helping to define identity. It is noteworthy that these developing interests and crushes are not sexually mature in nature. One must be alert to the fact that, as with preschoolers, if school-age children are preoccupied with sexual themes, it is wise to look for the possibility of sexually stimulating experiences, such as sexual abuse or witnessing of sex acts.

In middle childhood, socialization into gender role involves peer pressure and conforming to expectations, or else risking mockery. The individual also feels internal pressure to conform (13) (F).

There is a wide range of both timing and tempo of pubertal onset, and it begins for many girls near the end of what is traditionally termed middle childhood (G). Indeed, brain-related processes of puberty (including nighttime hormonal spiking and pituitary-hypothalamus feedback loop) starts for most young people during the ages of approximately 8 and 14. The visible onset of puberty from age 9 to 11, as measured through breast growth for girls, correlates with girls' positive body image, positive peer relationships, and superior adjustment (14). Conversely, a slower maturational pace may wreak havoc with social relationships, as peers re-align themselves with children who are perceived to possess more attractive or desirable traits.

It is well established that children adopt a firm gender identity by age 3 (15). This expression of their maleness or femaleness is manifested early by choices of role models and friends. With gender differences, as with so many of the other issues discussed in this chapter, the question of what is innate and what is the outcome of socialization remains intriguing.

A number of characteristics are associated with being male or female in the school-age period. Gilligan (16) (p. 9) cites Janet Lever's studies of 181 fifth-grade children at play. She observed that boys play outdoors in large and heterogeneous groups, and they play competitive games that last longer than those of girls (H). The games played by boys are full of disputes that seem to add interest to the interaction and do not derail the game. Similar observations of children playing led Jean Piaget to conclude that boys were more advanced in moral development because of their fascination with legal procedures and experience at generating fair arbitration of disputes. Many others concluded similarly that in the area of moral development and the development of the capacity to exert effective leadership in complex groups, boys preceded girls; few girls ever caught up.

In proposing that women listen to the demands of socialization and morality "in a different voice," Gilligan added new value to this "instrumental versus expressive" gender dichotomy. Gilligan's descriptions of different lines of moral development for

boys and girls will be discussed later in the review of moral development during school age.

Recognizing that boys generally develop instrumental functions and girls expressive ones, has provided explanations for other observed differences between boys and girls. In academic achievement, for example, girls traditionally tend to do better in verbal areas, while boys have done better in math and science. Even as the causes of these differences are being explored, they are also being denied and re-characterized. Feminism apparently has had its effects on gender identity and gender role behaviors in both girls and their mothers. For example, the widely held view that boys are more mathematically capable than girls has been demonstrated to be more an effect of socialization than innate capability (I). Math anxiety was related to gender-stereotyped beliefs of parents, the mothers being most influential (17). Furthermore, gender differences in academic skills that had been previously noted are now not found on many tests of academic competence (18). It is likely that other so-called innate gender differences will be similarly reevaluated in the future. Still, Gilligan et al. (19) in a Harvard research study, describe "hitting the cultural wall," when preadolescent girls realize that society values appearances more than accomplishment, they become more self critical and worry about their weight. A negative body image was found to be associated with high IQ. In the American Association of University Women's "Shortchanging Girls, Shortchanging America," a study of 3,000 girls and boys in 4th through 10th grade concluded that girls lose their positive self esteem and switch to appearance as the primary way to measure themselves (20). Other studies (21,22) support that preadolescent girls are more likely to get depressed, have their IQ scores drop, and decline in math and science.

Cognitive Development

The standard by which school-age children's cognitive competence has been evaluated is the achievement of what Jean Piaget termed "concrete operations." The preschooler's preoperational thought is a creative effort to grasp causality and make meaning of experience using idiosyncratic and egocentric logic. In contrast, school-age children master important operations that increase their objectivity and their ability to be conventional. Though we celebrate originality and creativity in our society, it can be argued that being able to be conventional enables children to participate effectively in their "society" whether it be peer group or the school at large. For example, many children who are referred to as "on the autistic spectrum," may be academically capable, even brilliant, but often may except themselves from listening to their classmates, doing their homework, or participating in classroom discussions. These exceptions may lead to increasing marginalization and eccentricity, and it appears that this is a highly sensitive time when such children recognize that they are different, may not have friends, as they would like, and

become quite sad and depressed.

Classification and conservation are the two crucial achievements of concrete operational thinking (J). Classification is the ability to group objects or concepts; conservation is the ability to recognize constant qualities/quantities of material even when the material undergoes changes in morphology. The concrete logical operations enable the child to deal systematically with hierarchies and categories, series and sequences, alternative and equivalent ways of getting to the same place, and reciprocal relationships. They include:

1. Composition—combining elements leads to another class (e.g., red and blue leads to purple)
2. Associativity—combinations may be made in different orders with the same result;
3. Reversibility—being able to return mentally to an earlier point in the process;
4. Seriation—the ability to create an orderly sequence along a quantitative dimension such as height; and
5. Decentration—simultaneously relating several aspects of a problem. This includes the ability to mentally picture another's frame of reference, which affects not only spatial reasoning, but also the potential for increasingly empathic understanding of another's point of view (K) (23).

Logical operations are crucial to mastering basic reading and mathematics skills, and they are also necessary for conducting social interaction, with its increasing complexity of groups, games, and rules. Acquisition of the ability to do conventional and objective mental operations is associated with an interest in the scientific workings of the birth process, and a grasp of the finality, universality, and inevitability of death.

Successful school-age children have not just the ability to perform the specific concrete operations themselves but also the ability to communicate about them in conventional ways. They understand that there are conventions of conversation, response to questions on tests, and social comportment. With cognition, as with almost every other aspect of the school-age youngster's development, joining society and sharing conventions are the keys to success. This interest in conventions and rules is frequently accompanied by a fascination with ordering and ritual. For example, school-age children often develop favorite numbers, magical rituals (Step on a crack, break your grandmother's back), or the need to do things in even pairs (L). They may also become collectors of coins, stamps, insects, baseball cards, comic books, etc. and may spend a great deal of time reviewing and ordering their collections.

During middle childhood, attention becomes increasingly selective. The ability to plan before taking action also develops (24). The school-age child's theory of mind (metacognition) is increasingly sophisticated, viewing the mind as an active and reflective information processor (25). Children become aware of their own mental

processes, private speech, and choice of memory strategies. However, school-age children are just beginning to develop cognitive self-regulation. One predictor of academic success is the ability to effectively self-regulate (M) (26).

Social Cognition and Morality

Along with the development of concrete operations during the middle childhood period of development comes the child's increasing ability to use these cognitive developmental changes to reflect on the self and on the social environment (27) (N). At approximately 7 or 8 years of age, social comparison becomes an important component of self and social cognition. Children's understanding of both social comparison and social relationships increases during this age period (27). A child's view of the self as comparable to or even ahead of peers on important dimensions will highlight belief in the self's agency and ability to be confidently "industrious," while a view of the self as lacking relative to the others can lead to feelings of inferiority (O).

Understanding of social relationships as described above leads to improvements in thinking about the complexity of social contracts, as well as moral and ethical obligations of the child and social group. A child's sense of morality, that is, the appreciation of consequences and justice, evolves from an egocentric idiosyncratic, and often harsh system of evaluations of behavior by punishment, to adopting internalized rules for evaluating behavior.

Piaget (28) posited that school-age children's morality is in the "interpretation of rules" stage. This accomplishment permits the child to understand the spirit of a rule and to make subjective moral judgments.

Kohlberg (29) described the moral development that most school-age children reach as the level of "conventional morality." Conventional morality contains two stages: "interpersonal concordance" and "orientation toward authority." In the stage of "interpersonal concordance" a child measures behavior and judges it on the basis of whether it pleases those he looks up to. These mutual interpersonal expectations are those of a "good girl" or "good boy," who wants to please her or his parents and teachers, and obeys the Golden Rule (Do unto others as you would have them do unto you) (P). The next stage in conventional morality, "orientation toward authority," reflects the societal values of duty, respect, and law and order. This differs from the stage of interpersonal concordance in that the child's moral compass is now set by the social system instead of the immediate social context of family, school, or neighborhood. The child supports the rules of society, believes that it is essential not to break these rules in order for society to function, and makes moral judgments based on how well an individual situation conforms to the rules of the social system (Q).

Gilligan's (19) studies of girls' and women's moral development led her to

emphasize the importance of relationships. In contrast to the traditionally masculine, seemingly quasimathematical system for evaluating moral choices, Gilligan finds that girls use a form of narrative that evolves solutions within conversations and interpersonal action. Thus, Gilligan interprets the fifth-grade girls' play observed by Lever (described earlier) not as poorly developed or socially immature but as valuing different aspects of the social experience. Gilligan describes the different responses of an 11-year-old boy and an 11-year-old girl, both of whom were at the top of their sixth grade class in a private elementary school in an academic community. The moral test question was that of the man whose wife is gravely ill and whose survival depends on receiving a specific medicine. The medicine is too expensive and the pharmacist will not reduce the price. The man breaks into the pharmacy and steals the medicine for his wife. In responding to the question of what should happen to the man, the boy thoughtfully weighed the problem of laws against stealing and a higher law valuing life. The girl, on the other hand, felt that the various parties needed talk to each other, and could not render an opinion about what should happen to him. She was aware of the rules, but felt that the conflict was such that mediation was needed to reach a resolution.

There has been significant critical reanalysis of Gilligan's data and conceptualization of the gender differences in moral reasoning. For both girls and boys, the development of morality reflects conventional thinking and measuring their evaluations with the rules of their society, as they understand them. Although moral reasoning continues to evolve through and beyond adolescence, many of the standards that are developed for our own behavior during middle childhood are likely to remain internalized and used as self-evaluation measures into adulthood.

Stilwell et al., in a study of 132 students aged 5 to 17 years, describe moral development as a natural outgrowth of attachment, evolving through five stages (30). First, the child's sense of security and experience of empathic responsiveness become paired with a sense of moral obligation. Next, the caretaker's rules are incorporated. Then, an understanding develops of how empathy can modify strict rule following. Next, ideals and role models are selected that reflect earlier learning in attachment relationships. Finally, the self is visualized as a keeper of moral standards. These stages roughly correlate with Kohlberg's stages of morality, but emphasize the grounding of morality and conscience in the early and fundamental experience of attachment and secure base, out of which empathy develops.

EMOTIONAL DEVELOPMENT

The most significant emotional issues in the lives of school-aged children concern personal worth that is determined by a sense of competence and place (in family, peer group, and communities). Competence is reflected in all of the places a child may live, at home by accomplishing tasks of caring for self (completing dressing,

including tying shoes) and at school by accomplishing the academic material presented (R). White (31,32) postulated a “drive” to competence that he felt to be as important as libidinal drives. In the school-age period, competence is not just experienced by the child succeeding at a task, but by others’ evaluation of his or her performance. Self-concept is derived from the self-knowledge and social comparison developments discussed earlier; self-esteem is related to the *meaning* ascribed to one’s competences and abilities (27) (S).

As Erikson warned, the emotional risk for the school-aged child is the possibility of feeling inferior if the child evaluates him or herself as not being able to accomplish tasks. This evaluation comes first from outside, from a teacher expressing disappointment or frustration, from other children laughing, from parents’ disappointment with grades or a teacher’s report. Increasingly through the school-aged period, children can evaluate their own performance and measure it against that of others. Failures in one area may be compensated by accomplishments in another, eventually, but the early school-aged child who has not yet learned about compensation, may just feel dejected. By the end of middle childhood, each child has constructed a composite evaluation of his or her own relative areas of competence and weakness, and has come up with his own answer to the questions, “What am I good at? Can I get the job done?” (T) It appears that emphasis on performance and assessment of one’s self in comparison to others can lead to a sense of inferiority and to more divisive interactions between children as they jockey for recognition and “power,” which is probably the source of bullying. How children negotiate these distracting competitive experiences lead to questions and feelings about themselves that tend to persist into adulthood.

The fears of a school-aged child are quite different from those of a preschooler. Because school-aged children are out and about in society, they are much more likely to witness or hear about catastrophic events that could happen to them (U). Their vulnerability to catastrophic fears is increased by the development, during the school-aged period, of understanding of the irreversibility and inevitability of death. Many school-aged children’s dreams reflect efforts to master these fears by setting themselves up as heroes who save whole families or communities from robbers, murderers, fires, storms, or other disasters. Children who don’t feel competent may be overwhelmed by these fears and have repeated dreams in which they are attacked and victimized and helpless.

Sullivan (33) was one of the first to emphasize the social influence on development. He described a series of internal processes by which the child gradually substitutes his or her own standards of evaluation for those of family members. Stimulated by models outside the family, these processes unfold throughout the early school period.

- *Social subordination* reflects a change in the child’s acceptance of authority from the specifics of personal caretakers to general categories such as the

principal, police, crossing guards, and teachers. The child first evaluates peers in terms of how they are regarded by these authority figures.

- *Social accommodation* is a process of acknowledging that there are differences between people. Early school-age children are intolerant of differences and can be cruel, but (with socialization and education) gradually differences may come to be respected.
- *Differentiation of authority figures* refers to the child's emerging ability to compare adults comparing parents to school-based authorities.
- *Control of focal awareness* refers to the child's response to social pressure to abandon some of his or her egocentric ideas and adopt a more conventional stance.
- *Sublimatory reformation* refers to the reorientation of focal awareness to the group-approved satisfactory behavior.
- *Supervisory patterns* reflect an awareness of one's behavior in groups. The supervisory patterns are almost like imaginary characters that develop in order to monitor oneself and eventually become internalized.

SELF IN SOCIETY

By the time they enter the school-age period, children have developed four basic areas of self-esteem: academic competence, social competence, physical/athletic competence, and physical appearance (34). As they progress through middle childhood, children continue to develop and refine their self-concept and sense of self-esteem, measuring and rating themselves within the context of their families, peers, and culture. The most salient achievement of the school-age period is a sense of oneself as a member of society. To accomplish this, maturation is required, as has been described. But the most significant arenas for advancing and refining the sense of self both in the present and in anticipating the future are the interpersonal arenas of family, peers, and school.

Home and Family

According to Heinz Kohut, the development of self occurs through a process of mirroring and idealization. In order to develop healthy narcissism, the child needs grown-ups to admire him and demonstrate attunement to his feelings (mirroring). The child also needs to be able to look up to his parents and other role models, and aspire to be like them without being unduly distracted by their faults and shortcomings (idealization).

Clearly, parents and teachers and other influential adults have important roles to play in how children view themselves. Baumrind (35) classified parenting styles according to "responsivity" (accurately assessing and responding to children's needs) and "demandingness" (setting high expectations) (V). Parents with high

responsivity and high demandingness ("authoritative" style) tend to have the best outcome, with children who do well academically and socially. Low responsivity/low demandingness describes the neglectful or uninvolved parent; and high responsivity/low demandingness describes the permissive parent. Low responsivity/high demandingness is characteristic of an authoritarian style, which may be predictive of a positive outcome in some minority families. Inadequate parental monitoring correlates strongly with a risk of delinquent behaviors, while parental involvement positively contributes to the child's cognitive and social competence (36).

The parent's optimal role in middle childhood may be that of a consultant or facilitator, coaching the child's development of his or her own skills and opinions, assisting as needed when help is requested, but allowing mistakes to be made and independent striving to occur in a supportive environment whenever feasible. This approach is congruent with an authoritative style, in that high responsivity and high expectations can coexist with allowing self-exploration on the part of the child (W) (37).

The "goodness of fit" (38) between parenting style and child temperament is constantly in flux. As the child encounters new challenges and develops new competencies, the parallel parental challenge is to be sensitive to the child's ever-changing needs, providing progressive responsibility and supervised autonomy as appropriate (X) (39). Recent research on genotypes and family relationships suggests that parent–child interactions are genetically influenced. Children's genotypes evoke specific parental responses; similarly, parental response patterns evoked by their children's particular behaviors show evidence of heritability (40). Targeted interventions can favorably alter these parental responses to difficult behaviors (41) hopefully changing their expression. The familiar social context of the family and neighborhood (that also includes extended family and religious communities with which the family may be involved) are altered in the school-aged period through several processes. The first is a practical one: when children spend more time in school, parents may spend more time doing things other than caring for their children. For parents who were already working, or who remain at home caring for younger children, or who choose to home-school their children, this may not be a significant change. In general, however, this creates a significant shift from the family organized for care of itself and its young children, drawn inward by primarily centripetal forces, to the more outwardly oriented family of adolescent children, where forces seem to be centrifugal, drawing family members out into interactions with the society at large (Y). Combrinck-Graham (42) described the decreasing centripetal forces of the school-aged child's family as "a house in the summertime; it is sturdy but has doors and windows open for circulation. Everyone comes in to share the family meal, to take shelter from the rain, and to sleep" (p. 147) (Z).

A second process that changes the family environment is the evaluation that comes

about from children bringing home their experiences with other children, other children's parents, and other adults whom they meet independently of their own families. Children make statements: John's mother lets him do this; Martha's mother doesn't do that; Sandy's father doesn't live with them (AA). Or they ask questions: Why doesn't Daddy stay home with us the way George's father does? How come you don't pick me up at school, Randy's mother does. Are we rich or poor? Are we Republican or Democrat? Why don't we celebrate Christmas? And so on. Or children reflect frank criticism: You don't know as much as my teacher. Smoking is bad for you; you shouldn't smoke.

A third process of family change is through children's relatively greater involvement in activities outside the home. Visits to friends, after-school activities, membership in clubs or participation on teams takes time out from family routines after school and on weekends. Adolescents are far more involved in activities outside the home, but most school-aged children's families have the opportunity to assemble for dinner and an evening routine that allows for completing homework and some form of age-appropriate bedtime routine (BB). Exceptions are largely due to complicated work schedules of caregivers who may work second shift or overtime. And in these situations, things go better if there is a reliable schedule, a supervising older person, and the opportunity to touch base during the evening.

A fourth process of family change is the possible social enrichment of all family life through involvement with the school as a community. This can be through socializing with families of other children, involvement in school and after-school activities, and through advocacy about school issues (e.g., PTA or participation on the school board). All family members, not just the children, usually become more involved in social experiences outside the family during the school-aged period.

Family/community relationships that have been stable prior to the school-aged period are subject to change in similar ways. In the early school-aged period children are developing skills that facilitate interaction with peers in the neighborhood (mastering a two-wheel bike; accomplishments in the pick-up sport of the neighborhood, such as soccer or basketball) (CC). Children may have different experiences with other children in the home area and in school. At home, in the neighborhood, a child may be included in a group of different-aged children and accepted because of familiarity or the relationships between the families. For example, children may be a part of a Sunday school group that is also part of the social context of the congregation. This peer group reflects the child's place in a family's place in a community. As the child grows older through school age in such a community, the child becomes more identified by distinct contributions to the community (such as participating in the music program, mastery of religious lessons, contributions to recreational activities) rather than just by membership in a family (DD).

Children may assume more distinct roles in their neighborhood society or Sunday

school group as they develop in school, or they may be less involved, as they become more interested in other things. Hobbies and collections are characteristic passions of school-aged children and often become the basis for formation of new social groupings. Social contacts may be conducted online as children come together around a particular interest.

The roles of television, video games, and cell phones, access to the Internet, and texting are beginning to be evaluated (EE) (43). While these forms of occupation, entertainment, and communication now have an established place in the lives of American school children and their families, such activities tend to isolate children from the daily commerce with their families and peers, and may stimulate an increasingly unrealistic view of life, one's role in it, and one's abilities. These activities may be comforting to children who are otherwise struggling either with learning, attention, or socialization, though this comfort may further cut them off from activities that involve them in their society. Kramer (44) explored some concerns about the role of TV watching in interfering with the "function of brains … to interact with each other to form families and societies," when he wrote about the biology of family culture. Finally, such activities are sedentary and often accompanied by eating, and there is increasing concern about obesity, diabetes, and other health problems associated with this lifestyle. The family dinner where everyone participates in conversation, everyone expresses interest in what others are thinking or doing is a model for participating in a community and being a valued participant. Face-to-face conversations have a different and important function than side-by-side texting communications. And, as noted above, the permission to "participate" outside of interaction may be comforting to the child who is socially awkward, but does not add to that person's becoming more comfortably "conventional," and more able to contribute to his/her community.

Peers

The peer group can be one of the most facilitating influences in school-aged children's development, or it can be disastrously inhibiting. As with other developmental tasks, each child brings a particular pattern of prior experience to the task of developing a social self. There is considerable evidence that peers themselves have their own attractions and that a substantial if not primary influence over a child's social self-development comes from the outside, predominantly through peer culture and its particular draw on the child's drives for mastery and competence. Robert White's (31,32) description of the growth of competence drives in the school-age period includes how to get along with others in the sense of competing, compromising, learning the rules of the game, and protecting oneself from injury. Sullivan (33) points out that other children afford an opportunity to do something interesting with the environment and that gradually the world of contemporaries competes with the family circle. Bemporad (45) describes the

juvenile era as a period between separation and procreation in which peers are the intermediaries. Erikson's focus on how children master industry overemphasizes individual achievement at the expense of cooperation. In a cross-cultural comparison, Kagan and Klein (46) credits the society of peers for advancing the development of children in San Marcos. He describes rural Guatemalan Indian infants and preschoolers who by all culturally relevant measures are "retarded" but who at 11 perform at the same level as American children in tests of cognitive functioning. The Guatemalan infant is unstimulated and left alone; only basic physical needs are attended to. Thus, Guatemalan infants do not have the assertive interaction with environment that is so prized in American infants and preschoolers. Kagan suggests that in the school-age period, where the relative neglect of these children by adults leaves them to form their own social groupings, Guatemalan youngsters begin to practice and learn assertiveness through jockeying for social position (FF). Grunebaum and Solomon (47) refer to Harry Harlow's studies, concluding that young rhesus monkeys leave their mothers because peer relationships are interesting, not because their mothers reject them. There has been debate about the relative influence of peer group versus parents on development, with some taking the view that the peer effect is significant while the parent effect is negligible (48).

Regardless of the relative weight placed on each of these factors, it seems that the drive for inclusion and acceptance, and the judgments of the other children that the child selects as his peer group, impact heavily on the school-age child's development of his own self-image and values. At the same time, the child's ongoing internal self-definition in turn influences his selection of peers to identify with and measure himself against. By around age 8, there has been a significant shift in a child's ability to assess his own skills in comparison to others, combined with feedback from parents, teachers, and peers. He begins to rank himself in various arenas, and combine these multiple assessments into his own ongoing "report card." This constant evaluation of self in social context becomes internalized into his own kinetic sense of identity. For better or worse, the opinions and descriptions we form of ourselves in middle childhood tend to continue throughout life. Personal "style," preferences, values, and self-assessment in comparison with others all have their foundation during the school-age period. How do children's attributions (explanations for why we act as we do) affect their self-esteem? Was their performance due to luck, ability, or effort? Children who make "mastery-oriented attributions" (49) give credit to their ability when they succeed (I'm great at math), and attribute failure to factors that are controllable (I need to study harder) or not fundamental (this was an especially tough exam). By contrast, children who attribute their failure to an innate lack of ability (learned helplessness) may develop a downward spiral in which they stop trying to succeed (50). Attribution retraining and help with self-regulation can be helpful, especially when started early (51).

Stages of peer development have been identified and described by Grunebaum

and Solomon (52):

- Unilateral partners and one-way assistance—the preschool child,
- Bilateral partners and fair-weather cooperation—middle childhood, and
- Chumship and consensual exchange—preadolescence (pp. 288–291).

The first school-age phase is characterized by membership in peer groups and is based on playmates' willingness and ability to play the way the child wishes. The second school-age stage (from about age 9) advances friendship to a closeness that Sullivan referred to as "chumship" with a peer of the same sex with whom an intimacy is formed, which paves the way for heterosexual intimacy and caring beginning in adolescence (GG). A study that examined second, fifth, and eighth graders' attitudes and choices for companionship and intimacy found that family members were the most important sources for companionship for both second and fifth graders. Same-sex peers were important throughout school age, but were increasingly important as the subjects grew older. Girls tended to report intimate disclosure to peers earlier than boys, and possibly reflecting that girls may value intimacy more than boys (HH) (53).

As peer interaction and the view of self in relation to others are vital to cognitive and intellectual development, so cognitive operations are vital to a child's emerging social self in the school-age period. Minuchin (54) points out that children move from games such as "Simon Says," "Mother May I," and "Follow the Leader," in which the children in groups follow the directions of a leader, to games in which the rules are set and governed by the players themselves, to games that involve contributions to the efforts of a team. This evolution involves shifts in the ways in which others are evaluated. Children begin the period by deeming others good if they give them things and bad if they take things away, and move to recognizing skills and personal attributes, to finally acknowledging and valuing social attributes, such as fairness (II). This shift, in turn, requires the expansion of perspective, which permits a child to see a situation from another's point of view. This decentering may be seen as a cognitive component to empathy and the development of more sophisticated morality.

With social development, as with intellectual development, preparation and prior experience are substantial influences. Patterns of behavior involving aggression are established early, and generalized aggressive disposition and the tendency to exhibit aggression in the context of specific relationships are quite stable (55). Aggressiveness is also associated with social rejection in the school-age period (JJ) (56,57). One view of the stability of aggression is that it is constitutionally determined. Another view is that aggression develops and is maintained in interpersonal sequences. For example, one researcher reported that "early-timing" mothers, those whose first children are born when they are in their 20s, have more difficulty setting limits on their children than "late-timing" mothers do (58). Children

of early-timing mothers are more likely to be aggressive, and in the absence of good limit setting within the family, the aggression becomes less amenable to social intervention. It is most likely that aggression levels are determined by an ongoing interaction of biologic tendency with psychosocial context.

Sociometric studies of school-age children yield up to five groups: popular, average, rejected, neglected, and controversial (59). There are two subgroups of rejected children, those who undervalue themselves and have low self-esteem, even in comparison to their teachers' evaluations of them; and those who have a positive view of themselves but are seen as defensive and aggressive (56). When children in different sociometric groups were asked to evaluate themselves and one another, it was expected that aggressive children would show attributional biases not shown by nonaggressive children. But, in fact these children's evaluations of others were not out of line, even though other children clearly identified the reputation of rejected children. Additionally, negative reputation increasingly separates the rejected group at older ages (57). Aggression and consequent rejection and social isolation during middle childhood is a primary predictor of maladjustment in later years. Rejected children often form social groups with other unpopular peers, which unfortunately may compound the problem by reinforcing poor social skills (60).

Contemporary reviews of peer relationships in the middle years point to the difficulties in researching this ever-changing set of connections. For example, peer relationships occur in a context. The grouping of children in a classroom may not be the same as how these children seek each other's company and friendship out of school. Furthermore, how children relate to one another in the classroom is very much affected by whether the educational style facilitates interaction between the students or not.

How children group, how large is their network, how popularity is related to friendship, all of these conditions of peer relationships seem to evolve through the school-age period, but researchers are still not clear about what are the best tools for assessing and therefore understanding the processes of peer interaction (61–63).

SCHOOLING

Schooling refers to the ecologic setting in which children learn. It refers to the environment, the size, the philosophy, the characteristic transactions between teachers and students, and the culture of the school. How the child *can* function, what he or she can do, how the child perceives him or herself, especially in terms of competence and the accompanying confidence to be able to accomplish, and finally, how the child is a part of communities/societies, all of these are substantially forged and reshaped in the school environment.

We will discuss four aspects of schooling:

1. Preparation: the effects of prior experience;
2. Attunement to children's learning styles and needs;
3. Concordance or discordance with the patient's family/community ethos;
4. How the school serves as a model for a community in which a child finds a role?

The Effect of Experience and Preparation on Children's School Functioning

Children arrive at school with diverse experiences. Most dramatically different are the experiences of children from middle-class, educated families and those from poor, minority, inner-city families. The former are more likely to have attended educationally oriented preschools, have traveled at least in their own communities, have visited libraries and museums, and have been read to by their parents and teachers (KK), while the latter have more likely been involved with complex family and "adoptive" family relationships ("play" mamas and many "aunts" and "uncles"), have experienced comings and goings of people in their daily worlds, and have been exposed to situations of danger and hardship with little sense of control over these situations. Children from immigrant families may not speak English, or, alternatively, may be the only members of their family who do speak English. Some minority youngsters may never have seen a book or a piece of paper or a crayon by the time they enter school. But many of them may have been assuming responsibilities in the household, such as caring for younger children, getting meals, caring for themselves while adults are away, and translating for their parents. The former group has been prepared to enter school since toddlerhood, while the latter group is prepared to manage an entirely different set of experiences, which may not be compatible with what is expected in school (64–66).

There is abundant evidence that the parents' education is related to children's achievement. Davis-Kean (67) researched this premise and found that this relationship is true of both White and African-American families. For both races, there is the indirect relationship through reading and providing a warm and supportive environment. White families also added a measure of expectation that was an additional incentive for their children's achievement.

There has been considerable exploration of the relationship between attachment style and adjustment to school (68) Granot and Mayseless (69) examined the relationship between attachment styles and adjustment in school, as measured by teacher ratings and student sociograms. Their sample of nineteen 10 to 12 year olds in Israel found that 66% were secure, 15% avoidant, 6% ambivalent, and 13% disorganized. As expected, the secure children had the highest adjustment scores and the fewest negative nominations on the sociogram. The ambivalently attached children were intermediate in scholastic and emotional adjustment and had the

highest number of negative nominations in the sociogram, corresponding with significantly lower levels of social adjustment than the secure children. Importantly, there was no relationship between attachment style and cognitive achievements.

Studies of the effects of model preschool programs and general application of Head Start programs for poor and minority children demonstrate that there is some advantage to having had a preschool experience, and this advantage is more dramatic and more lasting if the experience was in a model preschool program (70). In follow-up throughout the remainder of their school lives, children from model preschools were significantly less likely to be placed in special education programs than controls, but most often effects disappeared in 3 to 6 years, after the children entered formal public school (71). This suggests that preparation, alone, does not suffice to ensure a positive school experience. It is important to note that the most effective early education programs involved the parents in the school effort, so that the fit between home culture and school culture was enhanced.

Reading comprehension is largely thought to be text-based (i.e., content oriented) and interactional (i.e., develops within a relationship) (LL). It is increasingly evident that reading success is heavily influenced by the preparation of the reader, who brings to the task his or her expectations, prior knowledge of the content and structure of the material, and cultural background (72). Studies support this observation. One study reported that a group of 4 year olds given simple instructions in segmenting and blending words of two and three syllables 10 minutes a day for 13 weeks resulted in dramatically higher reading scores than those of children involved in nonspecific reading-related activities (73). Coles reported a study of the families of children with reading disabilities found that there is a significant lack of preparation of these children for reading. Other studies found that in some families, messages about expectations of failure were transmitted, while in others there were failures to provide exposure to preparatory material; in still others there was obvious evidence of "communication deviance" whereby the explanatory frameworks of language were so odd or idiosyncratic to the family that the child had unusual difficulty mastering conventional rules needed to learn to read (74). In addition to insufficient preparation, other etiologies of reading difficulty must be considered. These include learning disability (due to underlying processing deficits, auditory discrimination problems, decoding difficulties, etc.), intellectual disabilities, and knowledge deficits in oral language or vocabulary. Basic pre-reading skills include the ability to bring background knowledge to bear on a new situation, self-questioning behavior, and predictive skills.

Attunement to Children's Learning Styles and Needs

The second aspect of schooling involves the interaction around learning. Many use Vygotsky's ideas about the evolving mind in society to better understand how

children learn successfully. In this framework, learning represents the transfer of responsibility for reaching a particular goal (75). This transfer takes place in the "zone of proximal development (ZPD)," which is defined as "the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers" (Vygotsky, cited in Slavin (76) p. 1162). The ZPD is a useful measure of learning potential because it includes the instructional context (or, in the case of psychometrics, the relationship between child and examiner) as indispensable to the measured achievement. When children are presented with strategies, "strategy instruction" (whether children can adopt a strategy and apply it to other, similar situations without further instruction), those presented in the lower area of the ZPD are readily generalized, those in the midrange are adopted and gradually generalized, and those toward the higher end of the zone may not be adopted at all (MM) (70). The child's readiness, and the instructor's attunement to presenting material at a level that stretches already established abilities but is not so novel as to be overwhelming, are crucial to the "transfer of responsibility" that defines successful learning (NN).

Fellow students as well as teachers provide assistance with developing more sophisticated problem solving, as is stated in Vygotsky's definition of the ZPD. There are specific methods of peer involvement in learning that have come to be known as "cooperative learning." Cooperative learning refers to any number of types of student groupings for learning but differs from peer tutoring in that the material is presented by the teacher rather than by the peers. Students are given problems to solve or projects to complete, and the incentive to work together is encouraged by either rewarding the group's efforts, rewarding each individual child on the basis of the group's efforts, or rewarding the group on the basis of each child's achievement. Children can and will positively influence one another's progress. This is particularly true when some children in the group are more advanced than others, but it is also true when all children are struggling to master a new challenge. For example, using the Piagetian description of accomplishment of conservation, nonconserving children learn from peers who have mastered conservation, but they also progress in conservation skills when struggling with conservation problems with other nonconserving children (76). The process of working together must be specifically supervised and rewarded, because otherwise the more competent children take most of the responsibility for accomplishing the objectives or completing the project, while the less competent children do not contribute. But properly conceived, the value of cooperative teaching extends beyond the opportunities it creates for learning. It also provides a framework for learning about others, valuing differences, observing and utilizing the strengths of others, helping one another, and making a contribution to a community goal.

Regardless of the rate children learn and the specific strengths and weaknesses

they may have in mastering certain materials, attunement to each child's ZPD and pitching the new material to the appropriate level will inevitably enhance not only the child's success but also enthusiasm for learning.

Gardner's (77) theory of multiple intelligences suggests eight areas of aptitude with different processing operations and skill sets. These areas include linguistic, logical-mathematical, musical, spatial, bodily-kinesthetic, naturalist, interpersonal, and intrapersonal (OO). By expanding the traditional narrow definition of intelligence, this view challenges families and schools to help realize each child's unique potential.

Gardner's theory of multiple intelligences is echoed in Mel Levine's neurodevelopmental profiling (78). In these and other approaches being utilized in innovative educational strategies, the principle is that different children have specific learning styles. According to these theories, it is incumbent upon the teacher to ask, "How does this particular child learn best?" and to design an educational strategy that utilizes the appropriate mode.

Concordance or Discordance with the Patient's Family/Community Ethos

Two facets of congruence between the style of school and family as interfacing systems have been studied. The first involves expectations in the areas of educational goals, what is expected of the child, rules, and areas of permissiveness. Since the education system has been established by the majority culture, generally goals are congruent between school and majority families. Parents expect their children to attend school regularly, to be respectful, to be motivated, and to achieve. Problems come up when children can't or don't fulfill these expectations, which are ordinarily shared by family and school systems. They also come up, however, when these expectations are not shared by family and school systems. Then the all-too-common complaint that the child misbehaves at school but is fine at home, or, less commonly, the reverse, is brought to the attention of a counselor or mental health professional. This type of problem is most likely to be found in children from ethnic and cultural minority families and can be ameliorated when parents are intimately involved in school life (79). The second facet concerns the congruence of the way school and family systems are organized. In general systems terms, interpersonal systems can be open and relatively closed, referring to characteristics of freedom of exchange with other systems, definition of system boundaries, and amount of variety that is encouraged or tolerated within the system. Some schools that have been founded around specific religions are examples of closed systems, and these often serve a specific population with shared rules and values, constituting a good fit (PP). Rules about conduct, limits, and privacy are consistent across school and family and may differentiate each from the rest of society. Some schools have a more closed system

than many of the families of children attending. That is, the schools have clear rules and expectations about everything from dress to punctuality, while the families' own are more loosely organized. The school personnel tend to see these families as irresponsible and incompetent, and themselves as more capable caretakers. Open families sending their children to closed schools feel criticized and defensive, and a child is caught between the two systems, as he may want to conform to the school's expectations but depends upon the family to provide appropriate support. Open school systems allow for variability and have the potential of being flexible. But in many instances, open school systems interfacing with open family systems may have such a lack of definition that the children have no clear framework within which to define themselves. This kind of "congruence" between open family and open school systems often results in the involvement of the child with more systems, such as welfare, juvenile justice, or mental health (80).

Other aspects of the child and family's community relationships also support commitment to and investment in schooling. One study examining African-American students in different socioeconomic circumstances found that more important than poverty or prevalence of crime in a neighborhood was the effect of "collective socialization" (81). Collective socialization occurs in a community where adults recognize the children, speak to them, comment on their behavior, and will report to their parents or other authorities, if indicated (QQ). The study was primarily exploring the effect of collective socialization on conduct problems, and did note that in communities with collective socialization, there was a reduced risk for conduct problems. Schooling was a much more successful and valued part of the children's lives in these communities, as well.

How the School Serves as a Model for a Community in Which a Child Finds a Role?

A list of characteristics of effective schools includes strong leadership, an atmosphere that is orderly and not oppressive, teachers who participate in decision-making, school staff that has high expectations of students, and frequent monitoring of student progress (82). A specific aspect of school environment that has been studied is school size. It has been shown that large schools are often "overmanned," meaning that there are more students than role opportunities. This means that there are not enough opportunities in student government, arts, sports programs, or for individual distinction to recognize more than a very few children. In "undermanned" schools there are opportunities for students to be involved in activities and to take more initiative. The environmental role demands on the students in undermanned schools increase the levels of student participation so that they can contribute to the school community, develop identified roles in this community, and become known to themselves and each other as distinctive individuals. In large schools, there is the

danger of anonymity and ultimately a high rate of dropping out and involvement in antisocial behavior and substance abuse. The movement to consolidate schools thus increases the chances that students will not have a positive experience in school, unless the student population is broken down into smaller units within which students experience a manageable-size community (82).

Summary of Salient Features of Schooling

For school to be most effective at supporting the crucial development in school-age children, there has to be attention to the preparation children have had prior to entering school, and assistance to those whose experience has not primed them to take advantage of the school experience. Second, each child's learning style and readiness need to be understood sufficiently that educational material is presented that stimulates a child's drive to competence, without being so overwhelming that the child gives up. Most curricula are established to meet the levels of most children in the grade. But there are always children who are either more advanced or slower to whom learning tasks need to be thoughtfully and individually offered (RR). Thirdly, attention needs to be placed on the congruence between expectations of school personnel and that of parents. Involving parents in school activities is the most effective way to collaborate and close any gaps that could cause confusion and loyalty conflicts for the children. Finally, schools need to form manageable sized communities in which children can distinguish themselves. Even if the total school size is very large, there are ways to subdivide into smaller communities.

We have increasingly come to think of the school as a Learning Community in which the students' membership and identity must be nurtured and respected. The desired emphasis on students learning together in optimally sized schools and classrooms that allow for the recognition of each student's unique place and contributions to the Learning Community, as described above, is unfortunately not a conscious part of many children's educational experience. Particularly with the No Child Left Behind legislation (83) school curriculum and teachers' concentration have been focused on individual children's performance, because both the schools' and teachers' evaluations and federal funding are based on this. This refocus puts this very important community function of schooling at great risk, in our view (84).

There are cultures where children learn the "industry" of their society other than in school, primarily through various forms of apprenticeship (SS). Schools in our society offer both the opportunity for learning the "industry" and for learning one's place in society. We would be remiss if we did not point out that children in our Western society are privileged to have time set aside in their development for schooling. Although child labor is almost nonexistent in the United States and Europe, there are currently 250 million child laborers in the world between the ages of 5 and 14 (90% in Asia and Africa), living in extreme poverty, engaged in

repetitive and physically demanding tasks, who do not have the opportunity to go to school at all, and have limited opportunity to play and learn (85). One could argue that these children are also accomplishing the developmental task of learning the industry of their society.

FAILURES OF DEVELOPMENT IN THE SCHOOL-AGE PERIOD

From this discussion of normal developmental processes and influences on developmental outcome, understanding many failures of development is straightforward. Though maturational deviations or delays (such as developmental disabilities, or pervasive developmental disorders) may limit a child's developmental progress in all the spheres we have discussed, children with disabilities do and should achieve mastery of industry and the ability to participate in a community of school, peers, and subsequently adults at a level commensurate with their abilities (86). Though a family of children with disabilities may also develop differently, because of being more involved with their children and less open to the ebb and flow of peers and activities outside of the family, their children's school-age period does involve teachers, other educational professionals, and the families of other students, thus stretching the family very much as families are stretched for mainstream children. The challenge for mental health professionals who use a developmental approach in their work is to find arenas where handicapped children can be competent and interact socially. Lowering expectations of performance, providing ability-appropriate responsibilities for children to meet, and encouraging reciprocal social interaction are interventions that can maximize developmental accomplishments of these special youngsters.

Interference with learning may be on the basis of immaturity, or, as is more commonly diagnosed, due to disorders of focus, attention, impulse management, or specific learning dysfunction. Understanding the crucial developmental issues of establishing a view of oneself as a functioning person in a community can focus mental health consultant's attention on helping child, family, and teachers find strategies for managing areas of difficulty. Medication is often used to support such efforts, but is most effective when the child and the people closest to him or her are concentrating on competence and strategies for becoming competent.

Inferiority and defeat are the principal emotional pitfalls of school-aged children, because of the importance of mastery and recognition within the communities in which children participate. Depression is both a cause and an outcome of failure to progress in the manner that the child believes others expect. Assessment and treatment of depression in school-aged children must always include assessment of the developmental issues of competence and how a child is viewed by his or her peers so that in addition to psychotherapy and medication, assistance with social

functioning and academic mastery will be included. Disabling anxiety may occur as a result of either separation fears or performance worries. Both of these scenarios require that the school-aged child learn how to reassure himself (TT). The developmental challenge is to find a secure sense of self, moving comfortably between his nuclear family and his peer group, and setting reasonable internal standards for success in the face of external expectations. Externalizing behavior disorders drastically interfere with children's developmental progress in this era by disrupting learning and social accomplishment. Many such behaviors may be viewed as a defense against a sense of failure and inferiority (better to be seen as bad than dumb). Developmental approaches to treatment must include attention to academic progress along with several approaches to helping such children be accountable for their behavior. Behavioral management may be helpful (UU), but will be more so in this age-group if there are exercises in putting oneself in others' places and developing empathy, so that these children can function in society (Table 2.1.3.2).

TABLE 2.1.3.2

VIDEO CLIPS CORRELATED WITH CHAPTER TOPICS, TO ILLUSTRATE TEACHING POINTS

The video clips cross-referenced below are part of Dr. Fox's Normal Development Video Series, a DVD curriculum resource that follows the development of her two children in the context of their family and community over 20 years. Clips referenced throughout the chapter are either from *Normal Development in the First Ten Years of Life—Complete Version (FTY), or Normal Development in Middle Childhood and Adolescence* (MCA). Further information and sample video clips may be viewed at Dr. Fox's faculty website: http://www.psych.uic.edu/ijr/gfox.

Chapter Reference	FTY	MCA	Clip #	Age	Clip Title
A		x	67	14½	Info needed before a date
B		x	34	12½	Helping 8 y/o brother with homework
C	x		166	8	Sarah reads her "All About Me" assignment to her second-grade class, and tests their recall
D	x		165	7¾	Sarah and girlfriend discuss how boys have cooties
E		x	5	11	Fifth-grade matchmaking and gossip
F		x	122	7½	Brian is teased for riding his sister's hand-me-down pink bike
G		x	28	12½	"Five guys are fighting over me"
H		x	130	8½	Driveway basketball game
I	x		168	8¼	Sarah demonstrates math regrouping in subtraction, cursive, spelling
J	x x x	x x	201	7¼	David demonstrates conservation of liquid with Dr. Combrinck-Graham (compare with no.200 at age 5, preoperational).
			147	6¼	Coins versus money; conservation of length with pencils.
			168	8¼	Sarah demonstrates math regrouping in subtraction (using conservation)
			120	7½	Conservation of mass
			121	7½	Conservation of volume
K	x		196	5	Brian decides to let his pet "Tickles the Caterpillar" go
	x		173	9¼	Sarah writes and illustrates a story, "Sad Peggy," as a

					way to deal with losing her babysitter
L		x	128	8½	Lucky dice and home runs
		x	137	9½	Crime, restitution, conscience, and karma
M		x	20	12	Science homework rap
		x	25	12	Doesn't want to be viewed as "typical"
		x	46	13½	Positive self-talk to reassure and succeed
		x	142	11	Brian makes time smaller
N		x	37	13	How do other kids react to Sarah's awards?
O		x	153	12½	Brian reflects on his character traits and career goals
P	x		159	6¾	Sarah and two friends discuss moral dilemma (breaking plates)
Q	x		186	10½	Moral dilemma: should the church punish a reverend who conducted a gay marriage ceremony?
R	x	x	110	5	Brian learns to tie shoes
		x	112	5½	Brian reading aloud to self
			184	10½	Sarah shows her painting, discusses the process of making it
S	x		178	10	Doing homework with TV on, describes homework, test results, goals, creative writing.
	x		180	10	Discusses report card, focuses on the one grade that wasn't an "A"
T		x	71	15	Rewards for good grades—internal and external motivation
U	x	x	158	6½	Describes posttraumatic fears after home was burglarized
		x	17	11½	Mom soothing fears about going to sleep-away camp
			59	14	"If you had one week to live…"
V		x	22	12	Is Mom too lenient?
			129	8½	Brian gets allowance after cleaning his room
W		x	142	11	Brian makes time smaller (learning to manage his time on the weekend)
X		x	13	11½	Girls roam in packs, chase boys
		x	60	14	Is Sarah almost independent?
Y		x	62	14	Sarah never home, misses dinner
Z		x	87	16½	Studying together on porch during rainstorm
AA		x	15	11½	Girls plan outing, compare moms' rules
BB		x	123	8	Hates homework, loves Hedgie
CC		x	161	14	Makes high school soccer team, quits, rejoins
DD		x	23	12	Creates tap dance for school talent show
EE		x	118	7½	Turning off electronic games
		x	159	13½	Friends play Monster Hunter Freedom video game
		x	163	14½	Talk face-to-face or on Facebook?
FF	x		174	9½	Girls work out a group research project assignment
	x		177	10	Girls reading a play aloud, negotiating roles
GG	x	x	164	7½	Clapping game in pool with girlfriend and little brother
	x		181	10	Beth and Sarah sing "Stuff"—a song they made up
			21	12	Sarah and friend build hideout; Brian feels left out
HH		x	24	12	Does Sarah tell Mom everything?
II	x		167	8	Sarah receives $5 for a small box of candy, then refunds $4 because it was "too much"
JJ		x	16	11½	Why one girl is excluded
KK	x		76	1½	Reading Corduroy book with mom

	x		117	3	“Put-away time” at preschool
	x		137	4½	Sarah pretending to read to her new baby brother
LL	x		150	6½	Sarah reads Now I Am Six to mom
MM		x	127	8½	Brian divides by multiplying
NN	x		136	4½	Figuring out how to get hula hoop out of a tree
OO	x	x	155	6¾	Choreographs a dance on paper
	x	x	187	10½	Discusses art and tap interests, wants to be a teacher
			9	11	Tap class
			148	11½	Speed-stacking cups
PP	x		119	3	Teaching about charity at preschool—“Tzedakah” is the Hebrew word being defined
QQ		x	113	6	Skips Spanish class, gets caught in a lie
RR		x	37	13	How do other kids react to Sarah’s awards?
SS		x	149	11½	First summer job at farmer’s market
		x	150	12	Achieves lifetime goal as a kid
TT	x		157	6½	Sarah taught her beanie baby not to be afraid of heights, describes how she got over her own fear
UU		x	119	7½	Resists clean up after play date
		x	139	10	Kids describe their classroom behavioral management system

CHAPTER 2.1.4 ■ ADOLESCENCE

ROBERT A. KING AND HELENA J. V. RUTHERFORD

> *We are born, so to speak, twice over. Born in existence and born into life; born a human being and born a man.*
>
> —Rousseau, Emile

Adolescence in contemporary Western industrial society is shaped and defined by the interplay of complex biologic, cultural, economic, and historical forces. This lengthy transitional state, which may last a decade or more, is a distinctive period in which a youngster is no longer a child nor yet fully adult, but partakes of some of the challenges, privileges, and expectations of both epochs.

Adolescence is a period of paradoxes, as youngsters reach physical and sexual maturity well before they are fully cognitively and emotionally mature. On the one hand, a secular trend toward earlier puberty over the past century and a half means that defining maturational changes often begin by age 9 to 12, and that by 13 years of age, many youngsters are potentially fertile and sexually attuned, if not yet fully active. On the other hand, the educational demands of a complex modern economy have prolonged formal education and raised the age of mandatory school attendance to approximately 16 years, whereas social welfare concerns have abolished child labor and legally restricted adolescent employment, thus postponing entry into the world of work (1).

As a result, full economic emancipation usually is not possible until the later teens, at the earliest, and in the case of young people pursuing college or postgraduate education, often not until the middle to late twenties.

In the United States, the legal status of adolescents is a confusing mixture of privileges and strictures that attempts to balance the need for control and protection with the incremental granting of autonomy (2). For example, a 14 year old may fly a plane, but not legally drive a car, whereas a 17 year old may serve in the army, but not vote until 18 years of age, when he or she still is not legally allowed to drink. In many jurisdictions, a 14 year old may legally obtain an abortion without her parents' knowledge or consent but needs her parents' permission to be absent from school to do so.

Despite the restrictions on their full-time employment, young adolescent consumers are a potent economic force, controlling billions of dollars in disposable income annually. Teenagers, hence, comprise an eagerly sought-after demographic target for marketers, advertisers, and the broadcast, print, and electronic media. In turn, to attract and hold these young viewers and readers, media programming directed to them increasingly emphasizes sex and violence as prominent themes; sexual themes are estimated to make up approximately two-thirds of the content of

prime time shows popular with teens (3).

Winnicott once remarked aphoristically: “There is no such thing as a baby,” meaning that the baby could not be considered apart from its relationship with its mother (4). Although adolescence is the epoch *par excellence* of individuation and autonomy striving, it is similarly impossible to have a full understanding of adolescent development apart from its specific biologic, family, community, cultural, and historical contexts (5). Thus, while recent theoretical perspectives on adolescence acknowledge the development of *independence* and autonomy from parents, there is now an increased awareness of the complementary dynamic of the adolescent’s developing capacity for *interdependence* and the ability to form and sustain mutually supportive relationships outside the family. Paralleling this relational perspective is an increased emphasis on the *ecologic* perspective, which sees individual adolescents and their relationships as embedded in the interconnected contexts of family, school, neighborhood, and culture (6).

The interactions among these factors are complex and multidirectional. Not only are adolescents influenced by their families, but they reshape their families’ dynamics as they grow. Although important aspects of adolescents’ development are genetically and biologically determined, the effects of these determinants may be mediated or influenced by psychosocial factors. For example, family factors influence not only the impact of the timing of puberty but may actually affect the timing of puberty itself, with earlier and more rapid maturation in adolescents raised in more stressful, less supportive homes (7,8). Behavioral genetics studies that have revealed the importance of nonshared environmental factors suggest that adolescent siblings evoke different interactional and social environments even within the same family (9).

It is important to bear in mind the great diversity of social and family contexts in which today’s adolescents grow up (10,11). In the United States, despite some commonalities, the experiences of adolescents who are immigrants; gay, lesbian, or gender-dysphoric; or growing up in poverty, foster care, single-parent, or other nontraditional family structures differ in important ways from the general patterns presented later in this chapter. Even greater differences exist between the majority culture of the West and more traditional societies, with less emphasis on individual autonomy and fewer expectations that adolescence should be a period of vocational choice or attaining full independence from families (12). Some anthropologic studies have concluded that in such preindustrial societies, there may be less adolescent turmoil and conflict with parents (13).

One important research question concerns the impact on adolescence as the processes of modernization (demographic shift to longer life span, smaller families, urbanization, shift from agrarian to manufacturing and service economies, etc.) and globalization (with development of the Internet and an “information society”) expose more and more teenagers in such societies to the same media and cultural influences

as in the West (11–13).

One facet of globalization transforming important aspects of adolescence is the near-ubiquitous availability, at least in the industrialized world, of various electronic media, such as TV, video games, cell phones, and the Internet (including texting, e-mail, streaming music and videos, and social networking sites, such as Facebook, Instagram, and Twitter) (3). The Youth Risk Behavior Survey (14) found that 42% of high school students reported three or more hours a day spent on an average school day playing video or computer games or using a computer for something other than school work. A recent Kaiser Family Foundation Study (15) documented the relative amounts of time youngsters, age 8 to 18 years old, spent daily on these activities: 7.5 hours using entertainment media (consuming 10.75 hours of content because of multitasking). In addition to this media use, the respondents reported 1.3 hours texting daily. Only about one-third reported that their parents set rules about time spent on TV, videogames, or the computer. Over and above the sheer number of hours spent on these various media and their impact on youngsters' attention and cognitive style, youngsters are now exposed, for good or ill, and often without much adult supervision, to a plethora of global influences and virtual subcommunities, ranging from pornography to fellow aficionados of various videogames, cultural, athletic, or intellectual interests. Many adolescents now live much of their lives in an "online social context" and how this will influence their emotional and social development remains a vast experiment in progress (3,16,17).

PHYSICAL CHANGES AT ADOLESCENCE

The term *puberty* (from the Latin *pubertas,* meaning "age of manhood") is used to refer to the physiologic and morphologic changes that mark the transition from childhood to adulthood.

Hormonally Mediated Changes

The most visibly dramatic aspects of adolescence relate to the hormonally mediated changes of puberty: the development of primary and secondary sexual characteristics; marked growth in stature, muscle mass, and strength; and increased sebaceous gland activity. These changes are the result of three different sets of hormonal changes: (1) adrenarche, (2) gonadarche, and (3) increased growth hormone secretion.

Adrenarche, the steady increase in adrenally produced androgens, begins as early as 6 to 8 years of age, leading to increased skeletal growth and the beginning appearance of body hair even before the surge of gonadal hormones associated with puberty proper.

Puberty proper is marked by *gonadarche,* in which the pulsatile release of gonadotropin-releasing hormone produces increased pituitary release of follicle-

stimulating hormone and luteinizing hormone that in turn drive the production of gonadal hormones (primarily testosterone in boys, estrogen in girls) (7). Together with these gonadal hormones, increased release of growth hormone stimulates the pubertal growth spurt.

The triggers for this activation of the pituitary–gonadal axis are unclear, but have been speculated to include a variety of permissive signals, such as leptin or other metabolic indicators of adequate body weight/fat composition, interacting with a variety of genes and neural inputs (6,7,18).

The process of puberty takes approximately 4 to 5 years from start to finish, with girls (in the industrialized world) beginning the process on average at 9 to 11 years of age, approximately 2 years earlier than the average onset for boys. The various stages of this process, as indicated by pubic hair, breast development, height spurt, and menarche in girls, and pubic hair, penile and testicular growth, and height spurt in boys, have been classified by Tanner (19) into stages I through V.

The first harbinger of impending puberty usually is acceleration in linear growth, as much as 10 cm per year, which usually precedes increases in muscle mass and strength, thereby producing the gangling appearance of many early adolescents.

For girls, the initial stages of puberty are the beginnings of breast development (mean age 8.9 years [standard deviation (SD), 1.9] for African-American girls and 10.0 years [SD, 1.8] for white girls) and the appearance of pubic hair (mean age 8.8 years [SD, 2.0] and 10.5 years [SD 1.7], respectively) (20).

The clearest marker of puberty in girls is the onset of menses, or *menarche.* Girls' periods initially remain irregular for some time, and despite the high rates of early teen pregnancy, ovulation and full fertility may require 2 years to develop. Most modern girls have been well prepared for menarche by health classes, peers, and mothers, and news of who has (or has not) yet begun her periods is the topic of excited exchanges of confidences among middle school girls.

A critical body weight and fat/muscle ratio appears to be a necessary condition for menarche; hence, girls who train intensively for athletics or dance or who are anorectic may have delayed menarche. Probably related to the permissive role of adequate nutrition and body weight, there has been a steady secular decrease in the age of menarche since the Industrial Revolution, at the rate of approximately 2.3 months per decade (7,8). Currently, the average age of menarche is 12.9 years (SD, 1.2) in white girls and 12.2 years (SD, 1.2) in African-American girls (20). In recent years, there has been controversy about the appropriate norms for deciding at what age female pubertal development should be considered premature, since by age 7 to 8, a significant number of girls are already showing Tanner II breast or pubic hair development. Further study is needed as to whether this represents an increased prevalence of very early puberty in girls, and if so, what its causes and potential clinical implications are (7).

In boys, growth of the penis and testes and beginning spermatogenesis occur in

early and middle adolescence. In contrast to menarche, however, "semenarche" or the beginning of ejaculation, whether by masturbation or spontaneous nocturnal emissions, usually remains a very private matter among Western boys (21).

Detailed longitudinal studies reveal considerable variation in the onset and progress of the various stages of puberty, both within and between genders. Thus, peak growth velocity in girls occurs approximately 2 years earlier than in boys, whereas pubic hair appearance often is only approximately 9 months earlier.

Much research has examined the question of the developmental impact on adjustment of early versus late maturation in boys and girls (8,22). In general, these studies show that, for boys, although earlier maturation has some advantages in terms of popularity, self-esteem, and intellectual abilities, it also confers mild-to-moderate increased risk for internalizing symptoms and externalizing problem behaviors in adolescence but less risk for conduct or substance abuse disorders than their later maturing peers. For girls, the picture is more complex, with early-maturing girls tending to have more adjustment difficulties (including lower self-image and greater vulnerability to depression, anxiety, and eating disorders) and greater likelihood of engaging in risky behaviors and experiencing early sexual intercourse. The impact of early versus late maturation in girls, however, also depends on social context variables such as social class, pubertal status of peers, cultural norms, and timing of concomitant changes (e.g., school transition), as well as prepubertal adjustment (8,23). These studies are complicated by the fact that family disruption or stress is also associated with earlier onset of puberty in girls (7,8).

Neurobiologic Changes in Adolescence

Greater availability of neuroimaging tools has provided the opportunity of a window into the dramatic changes in brain morphology and functioning during adolescence.

One of the most dramatic changes in adolescent brain reorganization is a massive elimination or "pruning" of cortical synapses, with an estimated loss of up to 30,000 synapses per second during adolescence (24,25).

Synaptic pruning occurs throughout the brain, with significant regional variation in the volume and time course of pruning (26,27). This extreme pruning is thought to be adaptive, ensuring optimal connectivity between different areas of the developing brain (28). Increasing connectivity has also been observed in the adolescent brain through linear increases in myelin—the substance that insulates axons and facilitates the transmission of electrical impulses through the neuron (27). This growth in myelination is thought to improve the efficiency of neural communication throughout the brain, with increasing white matter being associated with improvements in cognitive performance across development (29,30).

In addition to these structural brain changes observed during adolescence, neuroimaging techniques have evidenced important changes in brain activity during

this developmental period. Several theoretical frameworks exist that bridge these functional brain changes to adolescent behavior (31–35), with all approaches evidencing agreement in the differential engagement of cortical and subcortical systems being central to adolescent behavior. In particular, these approaches posit that adolescence is a period characterized by delayed maturation of prefrontal and frontal cortices, neurobiologic regions that have been implicated in multiple cognitive control functions. Critically, concurrent to protracted frontal cortical development, increased activation in brain regions responsible for the processing of positive rewards have also been reported. One study found that adolescents, relative to children and adults, evidenced greater activation of the subcortical reward-processing structure, the nucleus accumbens (NAcc), in response to the receipt of large rewards (36). Reward-related activity in the NAcc has also been linked to an increased likelihood of engaging in risk-taking behavior across development (37). A recent longitudinal study also evidenced a peak in NAcc activity to reward during adolescence, with NAcc activity also being associated with risk-taking behavior as well as pubertal development and reward sensitivity (38). Consequently, this heightened responsivity to reward, coupled with decreased cognitive control, may represent underlying neurobiologic mechanisms subserving impulsivity, novelty-, and sensation-seeking behaviors typical of adolescence.

Neuroimaging studies have also evidenced increased reactivity of the subcortical emotion-processing region, the amygdala, to sources of negative emotions in adolescents. For instance, when viewing fearful as compared to neutral faces, amygdala activity was greater in adolescents as compared to adults and children (39,40). Furthermore, during an emotion regulation task, adolescents as compared to adults were less able to decrease amygdala reactivity to aversive stimuli through their employment of reappraisal strategies—with connectivity between the amygdala and prefrontal cortical regions during emotion regulation being associated with age (41). Therefore, delayed prefrontal cortical maturation may influence the capacity to downregulate emotional reactivity during adolescence. Critically, if these cortical regulatory functions are not fully developed, adolescents may be more susceptible to potential detrimental effects when experiencing negative emotions, including stress, which may be associated with the increased rates of psychopathology that have been observed during this developmental period. We will return to this potential source of adolescent vulnerability in the section on psychopathology.

Other Biologic Changes

Along with puberty come changes in appetite and sleep patterns.

Across species, the adolescence-associated growth spurt results in more time spent feeding and foraging for food. Most families with teenagers can attest to their youngsters' elevated metabolic rate and what has been termed *developmental*

hyperphagia (18).

Adolescence also sees a shift in sleep patterns, with a sleep phase delay or tendency to fall asleep later and wake up later (42). On average, 10- to 12-year-old children sleep approximately 9.3 hours a night and awaken spontaneously. In contrast, the mean length of sleep for high school students is 7.5 hours per night, with one-fourth of students sleeping 6.5 hours or less per night. Laboratory studies, however, suggest that the actual average sleep need for high school students is closer to 10 hours per night (43).

Part of this phase shift appears to be biologic; later night-onset and later morning-termination of melatonin secretion make it difficult for the adolescent to go to sleep earlier or to wake up alert in time for school, which, deleteriously for many teenagers, may begin as early as 7:20 AM. This shift in sleep patterns also has a psychosocial component. Adolescents are given greater autonomy by their parents in controlling their own bedtimes, while the expansion of social contacts outside the home and increased social stimulation (in the form of cell phone and social media) keep the teenager up later.

As a result of both these environmental and neurobiologic factors, many adolescents suffer from "too little sleep at the wrong circadian phase," especially on school days, with consequent difficulty getting up, frequent daytime drowsiness, and impaired alertness and cognitive functioning (43). Such adolescents are also at increased risk of learning difficulties, impaired academic performance, depressed mood, and accident proneness (44). In recent years, there has been a strong movement advocating for later school start times for high school and middle school students (45).

COGNITIVE CHANGES IN ADOLESCENCE

Adolescence is marked by dramatic quantitative and qualitative growth in cognitive abilities (46) with increased hypothetico-deductive problem-solving abilities and a greater capacity for abstraction. Adolescents' cognitive abilities are characterized by growing complexity, the ability to think about possibilities, and increased speed and efficiency of information processing. As a result, adolescence often sees the flowering of passionate intellectual and aesthetic interests, with impressive achievements in areas such as music, mathematics, computer science, or physics. Interestingly, adolescent works of genius are more commonly in these abstract areas than in those involving the empirical sciences or the humanities.

These cognitive changes also have their counterpart in the adolescent's social cognition and moral development (47,48). The development of formal operational thinking permits a growth in social perspective-taking and a decline in childhood egocentrism; it enables the adolescent to contemplate better what a social situation might look like from another person's point of view. Moral reasoning becomes more

complex and expands to include orientation to interpersonal relationships, maintenance of social order, notions of social contract and general rights, and, finally, reference to universal ethical principles.

Despite greater cognitive abilities, however, adolescents do not always use these capacities for sound decision-making, in part, perhaps, because their cognitive performance in real-life situations (as opposed to optimal test conditions) is more vulnerable to disruption by strong affects, everyday stresses, and peer influences (47,49–51).

On a practical level, the adolescent develops a more mature time sense, a greater awareness of the finality of death, and, along with wider knowledge of the outside world, a keener sense of the diversity and relativity of moral codes. This moral awakening may be accompanied by an intensified interest in and sophistication about politics, ideology, or religion. This wider vision, as most eloquently described in the work of Erik Erikson (52,53), provides both opportunities and hazards. Along with a penchant for philosophical musings, the adolescent may experience a sense of moral confusion and at least transient feelings of anomie. The anxieties of what Seltzer (54) has termed *frameworklessness* may lead some adolescents to a fanatical embrace of some ideology or religion on the one hand or a posture of nihilism on the other.

PSYCHOLOGICAL TASKS OF ADOLESCENCE

The physical, neurobiologic, and cognitive changes described previously herald dramatic shifts in the adolescent's relationship to his or her own body, appetites, parents, peers, and self-image. In this next section, we turn to the psychological tasks of adaptation these shifts impose on the developing teenager. Felice (55) has summarized these as:

- developing a satisfactory and realistic body image;
- developing increased independence from parents and adequate capacities for self-care and regulation;
- developing satisfying relationships outside the family;
- developing appropriate control and expression of increased sexual drives;
- identity consolidation, including a personal moral code and provisional plans for a vocation and economic self-sufficiency.

Coping with a Changing Body Image

Save for pregnancy or devastating illness, no other epoch sees such dramatic changes in the body and its self-representation as does adolescence. Although often welcome, these changes are also unsettling. Body and facial hair begins to grow. Menstrual discharges, erections, or ejaculation can occur at unexpected and embarrassing times. Acne and body odors make their appearance and are a source of anxiety. Boys'

voices may break unexpectedly as they deepen. Changes in the distribution of fat and muscle alter body outlines. Not only must girls deal with breast development, but, to their embarrassment, many boys develop gynecomastia.

Adolescents compare their development carefully with that of their peers and are acutely aware of their self-perceived imperfections. Much time is spent brooding in front of the mirror, examining every potential blemish and trying to catch a glimpse of the self. A single pimple may seem to loom as large as the Matterhorn, its stigma increased by the sense that it is as glaringly obvious to everyone else as it is to the adolescent.

Boys and girls differ in the extent and ways in which social factors influence their body image and notions of body ideal. In Western society, girls in particular are very preoccupied with the body image ideal of thinness held up to them by the media (3,56). Girls' levels of satisfaction with their bodies and physical appearance decline as they pass through adolescence; this is especially problematic for girls who are earlier maturing. While girls generally regard thinness as a goal to be pursued regardless of their actual weight, boys usually regard muscularity as the ideal at which to aim.

The Youth Risk Behavior Survey (14) found that although 32% of high school boys and 27% of girls were overweight or at risk of being overweight (defined as having a body mass index equal to or greater than the 85th percentile for age and sex), only 25% of boys thought they were overweight, compared with 38% of girls; furthermore, only 31% of boys were trying to lose weight during the preceding 30 days, compared with 61% of girls. In addition to media representations, ethnicity, social class, and perceptions of schoolmates' weight and habitus are also important determinants of both boys' and girls' body self-perceptions (56).

Pathologic eating behaviors are common in adolescents, especially girls. For example, a survey of two private girls' secondary schools found that 18% of the girls reported at least one major symptom of an eating disorder: 8% to 15% thought about food all the time, 6% to 12% induced vomiting to control their weight, over 2% used laxatives for weight control, and 7% often fasted or starved to lose weight (57). The national Youth Risk Behavior Survey (58) found that within the past month, 4.5% of high school students (6.2% of girls and 2.9% of boys) reported vomiting or taking laxatives and 12.3% (16.5% of girls and 8.1% of boys) had fasted for at least 24 hours to lose or control weight. These endemically high levels of body dissatisfaction and pathologic eating attitudes and behaviors provide a large reservoir of vulnerable adolescents from whose ranks those with frank bulimia and anorexia are recruited.

More research is needed, however, to understand better the cultural factors that influence the wide variations in the prevalence of disordered eating attitudes and behaviors across different communities and ethnic groups and over time.

The adolescent's body is also a representation of the adolescent's self. Hence, not

surprisingly, teenagers spend great amounts of time, energy, and money trying to make their appearance conform to some perceived ideal. Boys in middle adolescence may try to bulk up their gangling habitus or firm up a pudgy physique by weight lifting, bodybuilding, nutritional supplements, and even anabolic steroids in an effort to transform their self-image from weak, dependent, or vulnerable to that of a “hard body”—tough, masculine, and strong. Girls endlessly experiment with makeup and consult friends and websites regarding “makeovers.” Both sexes may go through a dizzying panoply of clothing and hairstyles, trying on in rapid succession a kaleidoscope of fashions and styles that also represent possible social selves: punk, home-boy, preppie, slut, grunge, jock, goth, and so forth. Multiple body piercings and tattoos convey more permanent, but potentially disfiguring personal statements. (By tattooing on a lover’s name, the bearer seeks self-reassuringly to reinforce the permanence of a relationship [49].)

Beyond its role as a source of anxiety or pleasure, the body also may be the vehicle for painful or self-destructive means of reducing psychic tension (e.g., through delicate cutting) or dealing with conflicts over dependency or instinctual longings (e.g., bulimia, anorexia nervosa) (60).

Changing Relations with Parents

Surveys such as those of Offer and Schonert-Reichl (61) have emphasized that most adolescents regard their relations with their parents as stable, trusting, and sustaining and continue to turn toward parents as important, primary sources of advice, comfort, and assistance. Although this appears to be objectively true for most adolescents, on a subjective level, there are important shifts in the emotional terms of the relationship for both the parents and youngster (23,62).

LOOSENING TIES TO PARENTS

Time spent with family decreases during adolescence, from 25% of waking hours for high school freshmen to only 15% for seniors (63). Furthermore, there is a shift in the affective tone of time spent with parents and in the adolescent’s view of the parents.

The teenager’s own parents often are de-idealized. This is a painful process for parents as their previously admiring child develops a keen (sometimes distorted, sometimes all-too-accurate) sense of their shortcomings. Even those many teens who retain warm and supportive relations with their parents experience an increased sense of loneliness because the youngster feels no longer able or willing to share many intimate concerns or longings as of old. The adolescent may alternate between wishes for autonomy and wishes to be taken care of. Feelings of dependency may have to be warded off with disparagement, indifference, or oppositionality (64). As a result, well-meaning parents often are bewildered as to which side of their child’s

ambivalence they are dealing with at any given moment (hence the titles to various guides for the parents of teens, such as *Get Out of My Life, but First Could You Drive Me and Cheryl to the Mall?* [65]).

CONFLICT WITH PARENTS

Csikszentmihalyi and Larson (63) remark that "friction appears to be an endemic feature of family life" in families with adolescents (p. 138), noting that "adults and adolescents live in separate, if overlapping, realities" (p. 140), often viewing the same events quite differently. This is true not only of specific events, but of family life in general, with adolescents tending to underestimate parental influence on them, and parents tending to overestimate their influence. Similarly, parents usually perceive the family's cohesion and adaptability as more satisfactory than do their teenagers who, in turn, report more conflicts with their parents than do the parents themselves (62,66).

Conflicts between parents and children increase with the beginning of adolescence. In early adolescence, these clashes concern household rules, chores, room cleaning, bedtime, diet, friends, dress, and hygiene; later in adolescence, issues such as dating and curfews become more prominent. Montemayor and Hanson's (67) naturalistic study of early adolescents found that conflicts with parents and siblings occurred at the rate of approximately 20 per month, or 1 every 3 days. Meta-analytic studies find that although the frequency of parent–child conflicts declines from early adolescence through late adolescence, the negative affective intensity of conflicts peaks in mid-adolescence (66).

Mothers appear to bear the brunt of most of these clashes, especially with early adolescent daughters (62,68); father–son clashes in particular take on greater affective intensity in mid-adolescence (66). Early maturation in girls and problems such as adolescent depression or substance abuse increase the likelihood of conflict (12).

This squabbling and bickering take a toll on the psychological well-being of the parents, as well as the adolescent, with many parents reporting difficulty adjusting to their teenager's strivings for autonomy (23).

The quality of daily family life thus becomes more turbulent in families with adolescents, with minor, but frequent "daily hassles"; for example, as boys approach puberty, there is a deterioration in family communication as both parents and child interrupt each other more frequently and explain themselves less (Steinberg, 1981, cited in 63). Time-sampling studies find that when with their families, adolescents' negative thoughts outnumber positive ones by 10 to 1 (63).

The apparent decrease in parent–child conflict in middle adolescence coincides with decreased time spent with parents and a turn toward greater involvement and reliance on peers, leading Laursen et al. (66) to speculate that "it is likely that

parents and children disagree less simply because they are together less. Increases in conflict affective intensity coincide with increases in autonomy and emotional dysphoria that occur as adolescents spend more time alone and with peers" (p. 828).

Despite the mutual stresses of increased conflict, most parent–child relationships remain solid. As Arnett (11) notes, "Even amidst relatively high conflict, parents and adolescents tend to report that overall their relationships are good, that they share a wide range of core values, and that they retain a considerable amount of mutual affection and attachment" (p. 320).

Seen from one perspective, the immediate *causa belli* of many typical parent–adolescent clashes appear seemingly trivial (what John Hill [quoted in 62] labeled "garbage and galoshes" disputes): hairstyle, clothes, chores, curfew, or time spent on social media or videogames. The intensity of conflict, however, usually reflects the parents' or child's perception (accurate or not) that vital issues are at stake: for the parents, issues of loyalty, respect, responsibility, and the dangers of sex, substance abuse, or other risky behavior; for the adolescents, issues of autonomy, control of their own body, and connections to friends.

Adolescents whose parents are able to hold firm and maintain balance in the face of these upheavals, without being overly permissive, harshly authoritarian, or indifferent, appear to do best. Numerous studies conclude that what has been termed *authoritative parenting*—combining warmth and responsiveness on one hand with firmness and demandingness—is associated with a wide range of adolescent competencies, academic achievement, and positive outcomes (62).

By later adolescence, in most cases, volatility and strife decrease and some degree of equilibrium is restored to the parent–adolescent relationship, albeit on a newer and more egalitarian basis, with the youngster having more autonomy and involvement in family decision-making.

TRANSITION TO SELF-CARE

As adolescence progresses, youngsters gradually claim or are ceded greater control over their diet, hygiene, sleep schedule, and dress, as well as responsibility for their school work. Nonetheless, these remain topics of frequent minor skirmishes, at least in early adolescence, with much parental nagging about junk food, skipped meals, slovenly or inappropriate dress, time spent online or on social media, and the like.

Although adolescence is a time of general good physical health, it also is the period during which many attitudes and habits are established with respect to diet, exercise, substance use, smoking, driving, and sexual behaviors that will constitute long-term risk (or protective) factors for health in later life (69,70).

Ironically, for many youngsters with serious chronic illnesses, such as type 1 diabetes mellitus or cystic fibrosis, despite their greater cognitive understanding of the exigencies of their condition, the quality of their care frequently deteriorates as

they take over the responsibility for adherence to their treatment regimen (71,72). Thus, many adolescent diabetic patients fail to adhere to their diet, blood glucose testing, and insulin regimen. Some chronically ill youngsters may stop their medication, including chemotherapy or immunosuppressant therapy, with potentially fatal consequences.

Unlike health-conscious adults, many adolescents perceive the need to pay extra attention to their physical condition as anxiety provoking, stigmatizing, or frighteningly threatening to their wish for autonomy and invulnerability; hence, rather than responding to their medical condition with heightened attentiveness, they may try to avoid thinking about or dealing with their illness altogether.

Developing Satisfying Relationships Outside the Family

As dependence on parents becomes less acceptable to adolescents, they turn increasingly to peers for companionship, advice, support, and intimacy (73). Csikszentmihalyi et al. (74) found that during the school year, adolescents spend one-third of their waking time talking with peers, but less than 8% of waking time talking with adults. Talking with friends was the activity that teens reported made them the happiest.

Parents may be bemused or annoyed by their adolescent's intense need to hang out with and be with peers, regardless of any family plans. This is not merely for the immediate pleasures of the event. Rather, the need for continuing access to peers is driven by an intense need to relate, to compare, and to try out aspects of the developing self. As Seltzer (54) points out, it is this developmental need that explains "why adolescents never seem to tire of being with one another…. [I]t is not the overt social activity or the content of the event (e.g., a rock concert, a football game, a dance) that feeds the drive. It is *being with one another*—looking, listening, and resultant comparing. Adolescents report details of who was there, what they did or said, and what they wore in far greater detail than they describe the content of the event" (p. 41).

With adolescence, the communicative, supportive, and intimate aspects of friendship take on increased importance. Although nonromantic opposite-sex friendships occur in later adolescence, close friendships in early adolescence tend to be with the same sex. Among girls, intimate conversations are most often the cement of friendships, whereas for boys, it tends to be shared activities. With age, the need for control and conformity decreases, and there is greater tolerance for differences between friends (23).

The choice of friends is a complex matter (73). Although the range of possibilities is defined by the given community and school population, the adolescent's specific choices of friends reflect an important and often fateful aspect of self-definition. Adolescents most often choose friends who share their behaviors, attitudes, interests,

and identities (23,73). Friends, however, also may be chosen on many other grounds, including perceived virtues or aspects of the self that the adolescent consciously repudiates or feels he or she lacks. Friends may serve as sources of support or admiration, as collusive companions for regression or delinquency, objects of sexual or aggressive exploitation, targets for projection—the list is endless. The choice of friend may be used to try on or borrow self-attributes; for example, a girl who perceives herself as unattractive or unpopular may hang out with a girl whom she sees as beautiful or popular. A boy who feels himself to be overly compliant, timid, or passive may choose to hang out for a while with a more venturesome or delinquent peer. Friendships pursued out of such interests may be transient or unstable as the youngster comes to feel in greater possession of the desired attribute himself or herself, or repudiates the wish for it.

Empirical studies have examined what personal attributes of peers are most salient to adolescents. For example, Midwestern high school students were asked to rate a list of attributes as to the frequency with which they were noticed in age mates. The top 10 attributes most frequently rated as "always of interest" were (in decreasing order): cleanliness, loyalty to friends, clothes, dependability, trustworthiness, general physical appearance, maturity, popularity with opposite sex, figure/build/physique, and honesty. Despite some gender and age differences, appearance and dependability were widely viewed as very important, whereas specific skills and abilities were of little interest (54).

Over the course of high school, adolescents shift in the gender and group size with whom they associate (73). Thus, freshmen hang out predominantly in same-sex groups, sophomores in same-sex dyads, juniors in mixed-sex groups, and seniors predominantly in small groups of heterosexual couples (63). In early adolescence, the adolescent's crowd consists of a large group of peers with similar reputations and role stereotypes (e.g., preppies, goths, brains, jocks, nerds). Younger adolescents value crowd affiliation as fostering friendships, providing support, facilitating interactions, and providing a source of identity and status (according to where the adolescent's particular crowd fits in the school or community hierarchy). Attitudes toward being "part of a crowd" do, however, change over the course of adolescence (73). Older adolescents are more likely to be dissatisfied with the perceived conformity demands of crowds and prefer smaller, more intimate groups. By the later high school years, the salient peer group may be the clique, a smaller group of peers similar in terms of activities, attitudes, status, age, and race.

Ironically, many adolescents, while resisting parental advice in the name of autonomy, are slavishly compliant with the perceived tastes and values of peers, especially regarding fashions and preferences in dress, slang, music, television, and movies.

Peers, however, influence each other in positive ways, including prosocial behaviors and academic achievement, as well as in negative ways, such as

delinquency or substance use (23). These influences are not necessarily coercive or conformist, but also stem from emulatory admiration and a community of attitudes and interests that form the basis for the friendship in the first place (73).

Adolescents' relationships with their parents are an important influence on peer relationships (62). Authoritative parenting styles appear to lessen the negative effects of peer influences; conversely, teenagers from less cohesive families are more likely to be influenced by peers than by parents (23). A tendency to look to peers rather than to parents for guidance and values, especially when combined with a choice of peers with delinquent behavior, low academic aspirations, or with values markedly divergent from the adolescent's parents, is an important risk factor for a wide range of problem behaviors (75).

Sexual and Aggressive Drives

Adolescence sees the epochal development of experiencing sexual attraction toward others and perceiving oneself as the object of others' sexual desire. How these subjectivities unfold and are given individual and social meanings is a complex process with physiologic, cultural, and individual dimensions (76). The interplay of these factors has been the focus of much anthropologic, psychoanalytic, and developmental study (72,77,78).

After a period of fairly open genital interests and play during the preschool years, overt sexual behavior and interests diminish markedly during the school years (79). Although even in these years before adolescence, sexual interests are never completely latent, masturbation, if it continues, is more furtive, and the child becomes more modest and inhibited about discussing sexual and romantic matters.

Beginning at approximately 10 years of age, feelings of sexual awareness and attraction make their conscious appearance (76). This development, which appears to be linked to rising adrenal androgens, occurs even before the onset of gonadal puberty proper. The reticence of children at this age makes the phenomena difficult to study in Western culture, but in many preliterate cultures, sexual rites of passage, at least for boys, occur as early as 10 years of age (78). It is also around the age of 10 to 11 years that some children become aware of same-sex attractions and homoerotic fantasy; feelings of gender-dysphoria, which may have been present from a much earlier age, become more distressing (80).

In early adolescence, genital excitement and sexual interests often occur independently of liking, intimacy, or wish for emotional closeness. For young adolescent boys, the objects of sexual fantasy and masturbatory excitement frequently are media figures or Internet pornography, rather than actual acquaintances. In keeping with their burgeoning attunement to social relationships, early adolescent girls are usually intensely interested in the romantic relationships, real and fantasied, of their peers, with endless discussions of who is "going out" or has broken up with

whom. However, the early teen boys who are their age-peers often are unpromising candidates as romantic partners, hence many girls' crushes and eroticized longings focus on media figures, such as the various "boy bands" marketed to this audience. Although movies and television have long provided the raw materials for adolescent sexual fantasy, it is not yet clear what the recent increases in the ubiquity, sexual explicitness, and violence of mass media (including now the Internet) will be on the sexual socialization of teens (76).

With adolescence, there also is a resurgence of overt sexual activity (76,79). The rate of explicit masturbation increases from approximately 10% at age 7 to approximately 80% at age 13 years, whereas that of heterosexual play rises to approximately 65% at age 13 years; homosexual play also is not uncommon in early adolescence, with 25% to 30% of 13-year-old boys reporting at least one episode of same-sex play.

The transition from childhood masturbation to that of adolescence involves more than an increased physiologic capacity for arousal and orgasm. Most teens report consciously fantasizing when masturbating to orgasm, and even those who do not seem aware of some sort of sexual imagery (77). Sexual fantasies (which also occur without overt masturbation) become an intense and important part of the adolescent's psychological inner life. Beyond serving as a source of pleasure and compensatory wish fulfillment in lieu of other sexual outlets, these fantasies provide the occasion for the adolescent to elaborate or explicate his or her idiosyncratic and personal erotic scripts: who, doing what, with whom, with what body parts, with what implicit and explicit emotional tone and interpersonal interactions, and with what admixture of dominance or submission, control or abandonment, sadism or masochism, and admiration or degradation. (Laufer [81] has coined the term *central masturbatory fantasy* to describe the organizing aspects of these not always fully conscious fantasies in relationship to arousal and orgasm.) These fantasies are more than just a form of rehearsal or anticipatory coping; they help the adolescent explore and become aware of what is pleasurable, anxiety provoking, transgressive, or deeply compelling in his or her longings and to become familiar with his or her own individual preconditions for erotic excitement and fulfillment.

A key task of adolescence is to bring these erotic longings adaptively into the interpersonal arena as a vehicle for intimacy, emotional closeness, and ultimately the formation of a stable partnership for the conception and rearing of the next generation.

Although early adolescence sees the transition from largely autoerotic sexual activity to sexual interactions with peers, this takes place at different rates in different social and ethnic groups and with different interpersonal meanings (72,76,77,82). The prevalence of ever having had sexual intercourse is about 24.1% in 9th grade and 58.1% by 12th grade, with higher rates among males (43.2%) than females (39.2%); the respective rates among black high school students are 48.5%,

Hispanic students 42.5%, and white students 39.9% (14).

For girls, the relational aspect of sexual involvement usually is paramount, and girls may engage in petting, oral sex, or intercourse as an attempted means of winning or retaining a boy's perceived interest, affection, or commitment. For young adolescent boys, sexual activity often has a more exploitative nature, with less interest in the relational aspect of the activity. However, these gender distinctions are not universal (76).

Falling in love is an important part of adolescence, even when not accompanied by sexual intimacy (6,76,82). Adolescence's most intense longings, keenest pleasures, painful frustrations, and bitterest disappointments center on the quest for a reciprocated love that helps to define the still inchoate self and assuage the loneliness of individuation.

Adolescent sexuality stirs in adults a variable reactive mixture of envy, apprehension, or repressiveness. Parents who may be facing their own midlife crises must contend with their sons' or daughters' burgeoning sexuality. Many of the parent–child conflicts in mid-adolescence, such as those around clothes, friends, dating, curfews, social media, and driving, although seemingly trivial, have the subtext of the parents' attempts to control the pace, scope, and direction of their adolescent's sexual activity. (A few parents who are overidentified with their adolescent's sexuality or take too much vicarious excitement in it collusively encourage their teen's transition to sexual activity.)

Despite much forgetfulness about the travails of their adolescence, most adults retain evocative, bittersweet memories of their own adolescent romantic longings. It is not surprising then, that from *Romeo and Juliet* on, the pangs and passions of adolescent love, whether thwarted or fulfilled, have remained an enduring theme of plays, novels, poetry, movies, and songs.

Identity

In his seminal work *Childhood and Society,* Erik Erikson (52) describes the challenge of identity formation as follows:

> [I]n puberty and adolescence all samenesses and continuities relied on earlier are more or less questioned again …. The growing and developing youths, faced with [the] physiological revolution within them, and with tangible adult tasks ahead of them are now primarily concerned with what they appear to be in the eyes of others as compared with what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day…. [It is the ability] to integrate all identifications with the vicissitudes of the libido, with the aptitudes developed out of endowment, and with the opportunities offered in social roles. [The desired outcome] is the accrued

confidence that the inner sameness and continuity prepared in the past are matched by the sameness and continuity of one's meaning for others (p. 261).

One of the most influential empirical extensions of Erikson's work was Marcia's taxonomy for classifying adolescents into four identity statuses: the *identity-diffused* subject who has not yet experienced an identity crisis or made a role commitment; the *identity-foreclosed* subject, who has made unexamined commitments, usually as received from parents and others; the *identity-moratorium* subject, who is actively struggling to define values and commitments; and the *identity-achieved* subject, who has resolved these crises (53,83). In contemporary Western middle-class society, many of these identity issues are not fully engaged until the college years or beyond (1).

Empirical research has shifted away from global notions of identity to focus more on the development of specific self-concepts (23,53,84). With their growing cognitive sophistication, adolescents' views of themselves become more differentiated and better organized. Harter (85) and others have examined the distinct dimensions of adolescents' self-concept across several realms, such as social relations, appearance, academics, athletics, and morality, and their relationship to global self-worth. Adolescents weigh these dimensions differently depending on whether they are interacting with peers, parents, or teachers, and it is only over time that that these discrepancies decline to produce a more consonant, better-integrated self-image. (Behavioral genetic studies of siblings suggest that heritable factors may exert more of an influence than do shared environmental factors on self-perceived scholastic and athletic competence, physical appearance, and general self-worth; self-perceived social competence appears to be primarily determined by nonshared environmental factors reflecting each sibling's unique family and social experiences [9,86].)

In addition to the generic categories of adolescent self-concept described by Harter, ethnic and sexual minority adolescents also must consolidate a sense of identity vis-á-vis both their minority group and the mainstream culture (23,53).

CLINICAL ASPECTS OF ADOLESCENCE

On the basis of many epidemiologic studies, it now appears that only approximately 20% of adolescents have diagnosable clinical disorders. However, it is equally clear that during adolescence, a substantial proportion of youngsters experience increased conflicts with parents and mood difficulties and engage in risk behaviors.

The Storm and Stress Debate Revisited

Historically, there has been a debate over the frequency and severity with which

adolescent turmoil occurs and the extent to which it should be considered normative in American culture or universal across epochs and cultures (for a review of this issue, see Muus [83] and Arnett [12]).

Although, over the centuries, adolescents have at times been idealized for their beauty and grace or as bearing the hope of the future, they also have been regarded by their elders with deep misgivings and dismay as potentially disruptive and subversive, not only difficult to handle, but threatening to undermine society's strictures regarding sex, aggression, and respect for elders.

The term *adolescence* was coined as recently as 1904 by G. Stanley Hall (87), who saw adolescence as intrinsically a time of "storm and stress," with "a period of semicriminality [being] normal for all healthy [adolescent] boys" (vol. 1, p. 404, quoted in 11). Speaking of the internal emotional upheavals of adolescence, rather than overt deviant behavior, Anna Freud (64) noted, "the upholding of a steady equilibrium during the adolescent process is in itself abnormal" (p. 164). She observed that:

> it is normal for an adolescent to behave for a considerable length of time in an inconsistent and unpredictable manner; to fight his impulses and to accept them; to ward them off successfully and to be overrun by them; to love his parents and to hate them; to revolt against them and to be dependent on them … to thrive on imitation of and identification with others while searching unceasingly for his own identity; to be more idealistic, artistic, generous and unselfish than he will ever be again, but also the opposite—self-centered, egoistic, and calculating (pp. 164–165).

In more recent years, the view of adolescence as inherently tumultuous has come under attack as an inaccurate overgeneralization from mental health professionals' clinical samples, from a romantic notion of youthful struggle (88), or from popular authors' vivid portrayals of their own idiosyncratic adolescent experiences. In contrast, seminal surveys of nonclinical adolescent populations by Offer and colleagues (61,84) have led to the conclusion that "adolescence is not a time of severe disturbance for all adolescents. Moreover, … a significant percentage of adolescents (80%) do not experience adolescent turmoil, relate well to their families and peers, and are comfortable with their social and cultural values …. [T]eenagers who exhibit little disequilibrium are normal … [and] … adolescence is a period of development that can be traversed without turmoil and that the transition to adulthood is accomplished gradually and without undue upheaval" (61, p. 1004).

This debate may turn on matters of degree (e.g., what type and severity of turmoil). In a review of the topic, Arnett (12, p. 324) concluded:

> [T]here is support for Hall's (1904) view that a tendency toward some aspects of storm and stress exists in adolescence. In their conflicts with parents, in their

> mood disruptions, and in their heightened rates of a variety of types of risk behavior, many adolescents exhibit a heightened degree of storm and stress compared with other periods of life. Their parents, too, often experience difficulty —from increased conflict when their children are in early adolescence, from mood disruptions during mid-adolescence, and from anxiety over the increased possibilities of risk behavior when children are in late adolescence. However… there are cultural differences in storm and stress, and within cultures there are individual differences in the extent to which adolescents exhibit the different aspects of it.
>
> [However], [e]ven amidst the storm and stress of adolescence, most adolescents take pleasure in many aspects of their lives, are satisfied with most of their relationships most of the time, and are hopeful about the future.

Having examined conflicts with parents, we turn to a more detailed consideration of mood problems and risk behaviors.

Mood Difficulties and Perceived Stress

Adolescence is a time of rising incidence for major depression, with the risk of depression and the preponderance of affected girls versus boys increasing not only with age, but more specifically with advancing pubertal status.

Only a minority of adolescents develop a full-blown affective disorder. Nonetheless, adolescence sees a marked increase in emotional lability, depressed mood, and negative emotions (e.g., anxiety and self-consciousness), with over one-third of adolescents in nonclinical samples reporting high levels of depressed mood (12,89–91). For example, the national Youth Risk Behavior Survey (14) of high school students found that, during the preceding year, 40% of girls and 20% of boys felt sad or hopeless almost every day for at least 2 weeks in a row that they stopped doing some usual activities and 23% and 12%, respectively, had seriously considered attempting suicide. Mood disruptions are associated with higher levels of negative life events (91,92). Comparing fifth graders and ninth graders, Larson and Richards (90) describe the dramatic decline in the proportion of time youngsters feel "very happy," "proud," or "in control" as an emotional fall from grace.

Girls appear especially prone to negative moods (91). For example, Offer and colleagues (84) found marked gender differences in emotional vulnerability across adolescence. Compared with boys, girls described themselves as moodier, sadder, lonelier, more prone to uncontrollable crying, more easily hurt, less autonomous and more other-directed, and more ashamed of their bodies.

Adolescents also report a substantial increase in the number of negative life events. It is difficult to determine to what extent this reflects a more stressful

environment, greater sensitivity to events, or shifts in the types of situations that precipitate negative emotions (91,93,94). The nature and sources of perceived stress change over the course of adolescence, with early adolescents experiencing stress in relationship to peers and older adolescents with respect to academic issues. Especially in early adolescence, girls appear to experience more stress than at other ages and to perceive more stressful events than do boys (93,95,96).

Although significant life events, such as parental separations or unemployment, moves, or deaths, have a serious impact on adolescents, many of the fluctuations in adolescent mood reflect the less dramatic daily hassles—homework, tests, disagreements with friends—the minor disappointments, stresses, and embarrassments that form the fabric of adolescent life. It may be deceptive, however, to try to conceptualize and quantify these hassles as completely independent external variables because unlike many major life events, the intensity, valence, and even the occurrence of such episodes often lie largely in the eye of the adolescent beholder (63).

Time-sampling studies of adolescent mood in community samples find that, compared with adults, adolescents have greater mood variability as measured by both the width of their mood swings (between extreme highs and lows) and the evanescence of these extremes (63). In the nonclinical high school population studied, greater subjectively experienced mood lability was not associated with poorer adjustment or other pathologic processes.

As noted earlier, developmental neurobiologic factors (including hormonal ones [91]) also may influence the impaired mood regulation and increased stress reactivity observed in adolescence (41,50).

A longitudinal study by Angold and colleagues (97) found that reaching Tanner stage III was associated with increased levels of depression in girls; however, hormonal levels of testosterone and estradiol were more closely associated with levels of depression than age or Tanner stage per se. Although this suggests that it is not morphologic body changes themselves that render pubertal girls more prone to depression, it is unclear whether these findings reflect direct depressogenic endocrine influences on the central nervous system or hormonally mediated changes in responsivity to life events and stress.

Spear (18,28) proposed that age-related changes in the balance of dopamine regulation in the prefrontal cortex relative to mesolimbic brain regions lead to shifts in the incentive value and motivational power of different reinforcers. Drawing on both human and animal data, Spear proposes a transient relative "reward deficiency syndrome" or "adolescent anhedonia" that results in previously pleasurable activities being experienced as less rewarding and leads to a compensatory search for new and more intense forms of stimulation (e.g., greater novelty seeking, risk taking, and increases in consummatory behaviors, such as food and drugs). Adolescents' decision-making about risks may be as good as adults under affectively neutral

conditions (so-called “cold” cognition); however adolescent’s prefrontal cognitive functioning and inhibition is impaired under conditions of even mild stress or emotional arousal (so-called “hot” cognition) leading to difficulty suppressing responses to appetive social cues; other aspects of adolescent brain development may further amplify these stress-induced deficits (35,50,98).

Risk-Taking Behaviors

Adolescent risk-taking behavior is a significant source of morbidity and mortality in this otherwise healthy age group. In contrast to persons 25 years of age or older, for whom two-thirds of all deaths are due to cardiovascular disease and cancer, three-fourths of all deaths for youths 10 to 24 years of age are due to motor vehicle crashes, other unintentional injuries, homicide, and suicide. Behaviors that increase the risk of these adverse outcomes are common among teenagers. The national Youth Risk Behavior Survey (14) found that for the 30 days preceding the survey, 6% of high school students reported rarely or never wearing a seat belt, 18% had ridden with a driver who had been drinking and, among the 61% of adolescents who drove, 41% had texted or emailed while driving and 7.8% of adolescent drivers had driven a vehicle when they had been drinking and 22% had driven having used marijuana. Over all, in the preceding month, 16.2% of high school students had carried a weapon, 32.8% had drunk alcohol, 18.5% had smoked tobacco, 21.7% had used marijuana, and 8.6% had attempted suicide in the prior 12 months. Other health-impairing behaviors also were common. About 41% of the students had had sexual intercourse; of these, 43% had not used a condom at the last intercourse.

These risk behaviors are not uniformly distributed across the adolescent population. For example, among ninth graders, 22% are estimated to be at low risk, with no involvement with any risk behaviors such as substance use, sex, depression/suicide, antisocial behavior, school problems, unsafe vehicle use, or bulimia (99). Another 29% report only one such risk indicator, 18% report two, and 31% report three or more. High-risk youth (those reporting multiple risk behaviors) are characterized by early onset of high-risk behaviors, absence of nurturing parenting, child abuse, lack of involvement with school, susceptibility to peer influence, depression, disadvantaged neighborhoods, and lack of gainfully employed role models.

Certain patterns of autonomic reactivity may also predispose to increased risk taking under certain circumstances (100), and data from nonhuman primates suggest important interactions between genetically determined variations in neurotransmitter regulation and early rearing environment (see below).

It is important to distinguish between occasional experimentation and persistent patterns of dangerous behavior (23). Although most adolescents will experiment with alcohol or minor delinquent behaviors, in most cases these behaviors do not persist

into adulthood. Studies in both human and nonhuman adolescents suggest that certain aspects of the neurobiology of the adolescent brain may make adolescents more vulnerable to substance abuse (101,102). (In turn, chronic alcohol, marijuana, or nicotine use during adolescence may have long-lasting deleterious effects on cognitive functioning). Human and animal research also suggests that certain personality and temperamental traits and genotypes may predispose adolescents to alcohol or nicotine abuse (102,103).

The prevalence of problem behaviors does increase in adolescence and early adulthood, but persistence in problem behaviors, such as substance use or antisocial behavior, usually is associated with difficulties in earlier childhood (104). The work of Jessor (75) and others (105) suggests that risk-taking behaviors such as sexual activity, substance use, reckless driving, and delinquency not only increase over adolescence but frequently are associated with each other and share common psychosocial antecedents. These behaviors are not simply arbitrary, perverse, or motivated only by sensation-seeking or exploratory motives, but are in part purposeful, meaningful, goal-oriented, and functional (106). For example, Jessor (75) observes that such behaviors also can serve the instrumental ends of gaining peer acceptance, establishing autonomy from parents, defying conventional authority, relieving anxiety or frustration, or affirming the transition to a more adult status.

Although the propensity to impulsivity, risk taking, and sensation seeking has important family and social determinants, it also appears to reflect the developmental immaturities in the neural mechanisms underlying inhibitory control, emotional processing, and executive functioning discussed earlier. Shifts in reward sensitivity occur early in adolescence and lead adolescents to seek higher levels of novelty and stimulation, while the more slow-maturing regulatory competencies that might check this novelty and stimulation seeking do not come online until later in adolescence (32,35,107).

ETHOLOGIC PERSPECTIVES

Examination of the transition from youth to adulthood in other mammalian (especially nonhuman primate) species suggests animal models for the counterpart of human adolescence. Like human adolescents, the young of other species exhibit increases in peer-directed social interactions and greater novelty-seeking and risk-taking behaviors (108). Spear (18,109) has suggested that these shared behavioral features represent ontogenetic adaptations that help individuals in this transitional period in “acquiring the necessary skills to permit survival away from parental caretakers. Increased affiliation with peers and the taking of risks via exploring novel areas, behaviors, and re-enforcers may also help facilitate the dispersal of adolescents away from the natal family unit” (18, p. 418), with the adaptive goal of avoiding inbreeding. Similarly, human adolescents and many pubertal nonhuman primates

spend increased time in social interactions with peers, including aggressive fighting, but also in reconciliatory and affiliative behaviors; paralleling this shift in social orientation from adults to peers is an increase in conflicts between the adolescent and parents, which also may help to encourage separation from the natal family unit (110,111). Increased risk taking also is seen across species, with increased exploratory behavior and novelty seeking, but also increased mortality. From an evolutionary perspective, such risk taking "may be—or at least once were—means of securing physical resources, attracting mates, and denying mating opportunities to competitors" (111, p. 117).

Research on nonhuman primates also provides clues about the complex interplay of heritable and environmental factors that shape risky behaviors during adolescence. Juvenile rhesus males with low CSF 5-HIAA are at increased risk to be expelled early from their natal troop and have very high mortality rates (46%) over a 4-year period compared to their peers with higher 5-CSF HIAA (0%) (112). Their high mortality rates (and unpopularity) reflect their excessively aggressive and impulsive behaviors, including inappropriate attacks on peers and higher-ranking adults and other risky behaviors, such as excessively dangerous leaps from tree to tree. Although 5-HIAA is a highly heritable trait in rhesus monkeys, it is also strongly influenced by early social experiences, especially attachment relationships, with peer-reared monkeys exhibiting lower CSF 5-HIAA levels throughout their life span than mother-reared counterparts. Gene x environment interactions are also apparent in the influence of early rearing conditions on the impact of other genotypes in adolescent nonhuman primates (103,113).

THE CLOSE OF ADOLESCENCE

The pubertal changes that are the hallmark of adolescence provide a relatively clear marker for the beginning of adolescence. In contrast, the close of adolescence in contemporary society is less clearly defined. At one time in the United States and even today in traditional societies, the end of adolescence and assumption of adult status was usually marked by a discrete event, such as marriage, beginning of full-time employment, or military service. Currently, however, the same forces that have helped to create adolescence as a distinctive period of life in industrial and postindustrial society also have blurred the end of adolescence (1,114). College and postgraduate education has become increasingly important, and the proportion of youth pursuing post–high school education has risen from 14% in 1940 to over 65% in 2014. Correspondingly, the median age of marriage in the United States rose from 21 years for women and 23 years for men in 1970 to 27 years for women and 29 years for men in 2010. Thus, for many young people, entry into adult roles regarding work, marriage, and parenthood is delayed until the late twenties or even early thirties.

Arnett (1,114) has proposed that the period from the late teens through the twenties be considered a distinctive period he terms *emerging adulthood.* In contrast to adolescents, 95% of whom live in a parental home, most young people age 18 years or older in the United States leave home, approximately one-third to live in a college setting and approximately 40% to live independently and work full time. Approximately two-thirds cohabit for a time with a romantic partner. However, despite high rates of residential mobility in the twenties, many young people retain some degree of dependence on their parents.

Hence, adolescence gives way to a prolonged period of quasi-autonomy and continued identity and vocational exploration that only gradually draws to a close in the third decade of life with the consolidation of an adult work identity, the capacity for adult friendships and a lasting intimate relationship, the emergence of a more mutual and equal relationship with parents, the integration of new attitudes toward time, and the beginning contemplation of parenthood (115).

2.2 DIVERSE POPULATIONS

CHAPTER 2.2.1 ■ CULTURAL CHILD AND ADOLESCENT PSYCHIATRY

G. PIROOZ SHOLEVAR AND SHASHANK V. JOSHI

INTRODUCTION

Cultural child and adolescent psychiatry consists of a body of theoretical and technical knowledge that informs high-quality psychiatric evaluation, treatment, and assessment of developmental process across cultural and language barriers to children, adolescents, and families. Clinicians are increasingly called upon to evaluate or treat patients from multiple cultural and linguistic groups. In our multicultural American society, treating a patient who speaks a different language or holds beliefs at variance with the majority culture requires the knowledge and skills that constitute cultural psychiatry (1). Cultural psychiatry defines the impact of culture on psychiatric evaluation and diagnosis, and provides guidelines for culturally competent and sensitive psychiatric treatment and systems of care (1–3). It is characterized by introducing the diversity of human experience into an understanding of the complexities of mental health and illness.

Cultural psychiatry has evolved consistently throughout the past century. Initially and at the beginning of the 20th century, it was primarily concerned with comparison of manifestations of mental disorders in different cultures and countries. It described the exotic and special features of different syndromes and disorders discovered in Africa, the Far East, and other non-Western countries. The descriptions were based on a universalist (and Western) viewpoint of psychiatry and mental disorders. In the mid-20th century, prominent anthropologists such as Ruth Benedict, Margaret Mead, and Bronislaw Malinowski incorporated psychoanalytic constructs into their cultural investigations of the impact of culture on personality development and disorders (4). This highly productive collaboration between psychiatry and anthropology also included Emile Durkhiem's landmark study on suicide and George Herbert Mead's Symbolic Interactionalist Theory.

The interest in sound methodologic measures in the mid-20th century resulted in the construction of a number of cross-culturally validated epidemiologic and diagnostic instruments. Recent findings based partially on such methodology have resulted in a gradual shift from a universalist viewpoint to a more culturally specific perspective (1,2,5).

The value orientation theory was originally proposed by Kluckhohn (6). It is based on variations in generalized cultural values. According to Kluckhohn, there are three possible variations in solution to the problems of time (past, present, future); activity (doing, being, being-in-becoming); relationship in groups (individual, collateral, linear); man–nature relationship (harmony-with-nature, mastery-over-

nature, subjugated-to-nature); and basic nature of man (neutral/mixed, good, evil).

Cultures vary widely in these dimensions. For example, American culture emphasizes a future time orientation, a "doing" mode of activity, an "individualistic" relational orientation focusing on autonomy; mastery over nature; and the nature of man as neutral or mixed. Using this now-dated typology, Spiegel (7) pointed how Southern Italians in contrast are oriented toward present, being, collateral relational view, subjugation by nature, and a mixed view of human nature, while Southern Irish are oriented toward present, being, lineal relationships, subjugation by nature, and the evil nature of man. In their views, the contrast between variable value orientations can create interpersonal tension and conflicts, such as in a cross-cultural marriage.

The *cultural relativist* perspective of current cultural psychiatry is in contrast to the *universalist* one, and asserts that cultural values and meanings are relative to and embedded in their cultural context, and cannot be measured against a universal system. It uses locally meaningful categories to describe indigenous syndromes, their phenomenology, and native explanatory models based on an ethnographic perspective (8). They make strong attempts to avoid the categorical fallacy.

Category fallacy refers to the application of a category that is valid within one cultural context to a culture where the category has no diagnostic validity or relevance. It stems from a universalist approach to assigning meaning to behaviors transculturally. In contrast, cultural relativists propose that cultural meanings and values are relative and fundamentally embedded in their cultural context. The latter perspective is referred to as *emic,* in contrast to the former approach, known as *ethic,* which applies Western diagnostic categories to another cultural context (8).

Definitions

Culture consists of those patterns of behavior, acquired and transferred over time, which prescribe the norms, customs, roles, and values inherent in political, economic, religious, and social aspects of family life. Culture provides the set of rules and standards that guide people's actions, makes their behavior understandable to one another, and helps to explain individuals' relationships to their sociobiological context.

Ethnicity refers to the sense of belonging and having a rootedness in history that reaches beyond religion, race, or national or geographic origin. Ethnicity is our basic identity—who we are in relation to other human groups. It frames our manner of dress, style, and communication through language and rituals, as well as how we feel about life, death, and illness (9,10). The concept is derived from the Greek work *ethnos,* or people of a nation. We are born with an ethnic identity. Throughout life we experience and adopt different cultures, thereby living with expectations and values from both a majority culture (i.e., the American culture) and minority culture—our

culture of origin. We carry with us both the values, assumptions, traditions, and worldviews transmitted over generations within our ethnic group and the concurrent—sometimes competing—view of the cultural context in which we live. As noted by McGoldrick et al. (10) and Herr (11), ethnic traditions still affect third and fourth generations in subtle ways and are often experienced as cultural conflicts between members of the younger generation.

Cultural context refers to the sociocultural environment in which people live and interact. The combination of ethnic origin and cultural context, together with the pressures imposed by cultural transitions and/or migration, inevitably creates difficulties that family groups must resolve. Landau (12) discusses the challenge minorities face in balancing the demands of living within two cultures—the culture of origin and the majority culture. She notes that if the stresses and differences are too great, the family network is too remote or too weak to help, the family must either adapt to the culture or turn inward on itself, becoming isolated and enmeshed as a family group. As a consequence of the ethnocentric defense, very often the family resists accepting help from outsiders unless their problems become too great to handle alone.

Cultural identity refers to the patient’s cultural or ethnic reference group and the degree of involvement with both host culture and culture of origin. This internalized self-definition selectively incorporates values, beliefs, and historical elements from those available in the person’s environmental values and contains self-experiences related to ethnicity, gender, values, and a wide range of beliefs.

Ethnic identity describes a sense of commonality transmitted over generations by the family and reinforced by the surrounding community (10). An ethnic group is defined as “those who conceive themselves as alike by virtue of their common ancestry, real or fictitious, and who are so regarded by others” (13). It is perceived as “we” in contrast to “they.” Ethnic identity develops as the product of ethnic socialization by children acquiring the values, attitudes, behaviors, and perceptions of an ethnic group, and perception of themselves and others as members of the group (14).

Cultural mask, as described by Montalvo and Gutierrez (15), refers to the family’s use of real elements in their culture to conceal their problematic behavior and interactions. For example, the family can use the rationale: “We are Latin, we are expected to have hot tempers.” The family thus uses culturally sanctioned behavior in a defensive fashion in order to protect crucial underlying issues. The family presents to the therapist a view of who they are based on what they think is expected of them, instead of showing how they actually behave when trying to resolve problems or even interact with one another. Montalvo and Gutierrez caution the therapist to search for the problem-solving approach of the family and not get caught up in exotic or unusual behavior patterns unique to the family’s culture.

Culture-Bound Syndromes

Culture-bound syndromes consist of disturbances in mood, behavior, or belief systems that appear restricted to a particular cultural context. They are frequently viewed as exotic or covert illness phenomena occurring in the context of a local culture. Many culture-bound syndromes have been described worldwide. For example, some syndromes can exhibit acute episodes of anxiety, such as *ataques de nervios* in Latin America or Koro in Malaysia. The former syndrome manifests by trembling, shouting, crying, fainting, seizure-like activity or suicidal gestures. The person may return to normal functioning rapidly. As with many similar syndromes, it is a pattern of behavior that is understood locally as a meaningful manifestation of distress, acceptable within the cultural context. Such symptoms signal distress and activate a culturally specific response to the situation. The symptoms are recognized and interpreted through the appropriate attribution, which is part of the common socialization process for the cultural subgroup (8).

Acculturation

Acculturation refers to the process of behavioral and attitudinal changes in a cultural subgroup as a result of exposure to the practices of a different dominant group (16). Initially, it was hypothesized that a high level of acculturation decreases stress and the risk of psychological disorder in members of cultural subgroups. Subsequent studies have further recognized the complexity of the process; the concurrent relationship between a high level of acculturation and increased psychological distress is likely due to social role conflicts and the partial loss of traditional support received from the original culture (1,17,18).

The culturally sensitive clinician can be well-served by paying close attention to the unique experiences of each individual in the acculturation process as it is manifested by intense rejection or blind acceptance of cultural elements of the host or original cultures, or a resistance to assimilation into the broader culture. The complexity of the acculturation process in child/adolescent and family psychiatry can be significant because of different levels of acculturation achieved by children and their parents. Children born in the host country can achieve a very high level of acculturation, while parents may adhere strongly to the practices of their original culture and reject the values of the host culture. Fathers may develop a much higher level of linguistic and cultural competence due to their workplace experiences in contrast to some mothers, who may not learn the new language and cultural practices if primarily functioning in the household. The level of acculturation of younger children may also differ significantly from that of older children, particularly if born and initially raised in the previous culture and exhibiting sharp differences from their younger and Americanized siblings. The degree and nature of the acculturation

process can be determined by inquiry into age at immigration, number of years in the United States, language proficiency, and participation in the host culture's social activities and social networks (1,16). The term *enculturation* is also sometimes used to refer to this process in which children and teens learn about, and often incorporate, the societal norms in their cultural environment. This process may be influenced by peers, parents, and other adults. If the enculturation process is successful, the language, values, and rituals of that culture will be incorporated into the individual's worldview (72). Ideally, an optimal degree of biculturality will be achieved, whereby the young person incorporates the best of their parents' (or their own) culture of origin with those of the present (host) culture. Multiracial adolescents may face a more difficult challenge than their monoracial peers in that they must develop this new identity and decide how, or even if, they can reflect positive aspects of all heritages while also rejecting certain societal expectations and stereotypes (74–76). Often by adolescence, multiracial children have been made aware of any racial/ethnic differences between classmates and themselves. They may be reminded of these differences as they attend school and are asked questions such as "What are you?" from classmates puzzled or threatened by their racially or ethnically mixed appearance. These alienating questions often contribute to the feeling that no one understands them, not even their monoracial parents, as they may feel "stuck" between cultures (74,77). Concerns about not "fitting in" are magnified if multiracial adolescents find that they are no longer welcome in certain peer groups because of racial issues (e.g., family objections to interracial romantic relationships; 77,78). Additionally, some peers, and even their own parents, may pressure the adolescent to identify with only one ethnic background, prompting feelings of guilt or disloyalty (74,76,82).

Incongruent cultural values and language skills among immigrant parents and their acculturating offspring can lead to an acculturation "gap." This gap between parent and child has been termed acculturative family distancing, or AFD (83). AFD is defined as the distancing that occurs between parents and youth as a result of communication difficulties and cultural value incongruence, and has been studied extensively in Asian and Latino immigrant families, though it may have broad applicability to other cultural groups (83,84). AFD is intensified by parent–child acculturation differences. Specifically, parents and children may give up their heritage culture at different speeds and acquire the characteristics of the host culture at different rates. High AFD (i.e., a large acculturation gap) has been associated with increased intergenerational family conflict and decreased family cohesion in Asian American and Latino adolescents (85–87). AFD and its core domains (communication difficulties and cultural value incongruence) are hypothesized to increase over time and lead to distancing between parents and youth, thereby increasing risk for family conflict, which, in turn, increases risk for depression and other psychological problems (84–85). On the other hand, a sense of an integrated,

bicultural self-concept may allow enculturated youth to persist through periods when they may experience rejection from one or both cultures (81,87). Several authors have highlighted important psychological features of healthy biculturalism (73,74,79,80) because it creates a sense of cultural self-efficacy within the institutional structure of society, along with a sense of pride and identification with one's ethnic roots. LaFromboise (79) proposes that it may also have much to do with parental modeling of this construct, and can be directly related to how well the parent has either *accommodated* the new culture (adopted certain aspects of the new culture, while still retaining important features of the root culture, or culture of origin) or *assimilated* the new culture (adopted most or all of the new culture, while having cast off the previous cultural values and belief system).

Effect of Culture and Ethnicity on Child Development

Recent trends have brought the cultural context of child and personality development into bold view. Among these are the global demographic trend toward cultural heterogeneity, and contributions from cross-cultural psychiatry and psychology. It is generally established now that culture influences the development of children and shapes personality from infancy through adulthood. The child-rearing practices of parents and family provide the infant with the basic nurturance needed for development. Equally important is the role of parents and family in transmitting cultural rules, standards, and values to the child through the process of socialization. Cultures vary widely and differ from each other in the way the tasks of socialization are carried out, the specific rules and values transmitted, and the behavioral and conceptual outcome of socialization process with regard to beliefs and worldviews adopted by the children (19,20,21,74).

It is also firmly established that much of our information on child and adolescent development is based on norms that are almost exclusively Western, middle-class, and male oriented. Most of the observations and studies have been conducted in Western settings and are nonrepresentative of the world's population. These studies perpetuate a given view of the universe and tell us little about how youth develop in so-called "minority cultures" in Western societies (22,23). Child-rearing practices vary widely in different cultural domains. In many cultures, particularly Western ones, the main parenting person is the mother, with the father assuming an important but secondary parental role. In African societies, older siblings assume a significant role in raising infants and young children. Other family members and grandparents assume important child-rearing roles in Asian and other cultures. Other caretakers offer the children a different or expanded view of the world (24,25). Socialization occurs not only through explicit teaching but also through day-to-day experience of childhood and through the structure of the settings where the children live and play.

Cultural Impact on Developmental Stages

Examinations of the influence of culture on differing developmental stages is gaining interest among investigators. We briefly review the investigations of several developmental stages.

Cross-Cultural Research on Infancy

A strong theme in literature is the "precocity" of babies from traditional, nonindustrialized societies. They may stand or sit 2 to 4 or more weeks earlier than American and European norms. At times, the precocity in Africa has been linked with reports of precocity at birth. The clusters of advanced behaviors are to a large degree correlated with environmental factors (26,27).

Putting aside the multiple and complex methodologic issues in many studies, it is generally established that African babies reared in relatively traditional ways achieve many motor functions, particularly in the first year of life, before their European and American counterparts. The findings from studies in Uganda have been subsequently supported by multiple studies in other African countries (26,27). The advanced skills frequently coincide with deliberate teachings of the infants by the mothers and other caretakers of how to walk, sit, and help the babies practice those skills. They may use props to facilitate those tasks. The encouragement of sitting and carrying the baby on the caretaker's back is more helpful in the development of trunk, buttocks, and thigh muscles in comparison to having the child sit on an infant seat (26,27,29). Similar findings have been reported in Asian countries, including India (28).

Lester and Brazelton (30) propose that African child-rearing practices are built on the infant's responsiveness to being handled in the neonatal period and facilitate motor precocity. Motor excitement of infants may elicit engagement and interpersonal handling from the caregiver, thus enhancing developmental progression. Normal infants in different traditional cultures appear to exhibit critical cognitive developmental levels at about the same time throughout the world (26,30).

Temperament

In studying temperament, cultural affiliation is a strong predictor of infant temperament in the first year of life and is exquisitely sensitive to environmental influences. McDermott (25) has proposed that temperament should be viewed as a constellation of traits with a threshold of expression that varies from culture to culture. Considering two broad clusters of temperament, namely rhythmicity and activity, significant cultural variations are evident. Chinese American, Japanese American, and Navajo Indians are temperamentally less excitable than other groups who exhibit lower levels of arousal and are easily consoled. Mexican Indians and

Kenyan infants have smoother transitions from one state to another and maintain quiet, alert states for longer periods and are higher on motor maturity (25,31,32).

Examining the investigations of Jerome Kagan (33,34) on shyness and social/behavioral inhibition, McDermott (25) proposed that cultures impart meanings to the behavior but also determine how others perceive and react to the behavior. Inhibited and shy children are more readily accepted by mothers in the Chinese culture, in contrast to their North American counterparts. Shy–anxious children in China are valued and accepted by society and peers, and adjust well to their social environment (33–35). In the West, shyness and social withdrawal are associated with peer rejection and isolation, reflecting a stronger emphasis in the West on the need for self-expression and self-confidence (33–35). In contrast, the ready acceptance of these biologically determined traits and behaviors by parents, teachers, and peers in Asian culture reflects a low level of apprehension about these traits. McDermott proposes that Chess and Thomas's model of goodness-of-fit be applied at the cultural as well as the individual level.

The first large-scale investigation of children living in multiple cultures was undertaken by the anthropologic team of Beatrice and John Whiting (36,37). They compared the behavior of children and the adults' expectation of them in six different cultures: India, Kenya, Mexico, Okinawa, Philippines, and the United States. Children in nonindustrialized cultures were given tasks important to the well-being of the families, such as caring for younger siblings and tending to a goat so the family did not go without milk. Children showed nurturing and responsible behavior. Children in industrialized cultures were not expected to contribute to their family's survival, were more self-centered and dependent, and their self-centered orientation was tolerated by their families. The self-centeredness may be actually an asset in Western cultures and enhance the desire for personal profit (19). Whiting and Whiting found the influence of peers on young children to be very powerful and occur early. Additionally, parental efforts to control and redirect the aggression of their children emerged more strongly than their nurturance in all of the above cultures (25,36,37).

Attachment

Previous work in cross-cultural development and attachment has proposed that aspects of this construct may be very culturally dependent (74,107–109). For example, the degree of emotional intensity and its projection to a single primary parent, considered an underpinning of object relations theory, may be more typical of Western culture (versus multiple caretakers in many non-Western cultures) (107). Other outgrowths of Western concepts of attachment include the development of transitional objects (108) and the process of psychological hatching, or separation–individuation, as critical to psychological health (109). Evidence shows that all of these concepts in psychological development are variable across cultures, and in

some cases even culture-bound. For example, Bornstein and colleagues (110) examined and compared characteristics of maternal responsiveness to infant activity during home-based naturalistic observations of mother–infant dyads in New York City, Paris, and Tokyo. They found that differences in maternal responsiveness across these cultures occurred in response to infant looking (at the mother) rather than infant vocalization, and in mothers emphasizing interactions within the mother–infant dyad, instead of outside or beyond the dyad (74,110).

Being part of a group, rather than individual assertiveness, is highly valued in many cultures. Being agreeable, respectful, emotionally mature, courteous, and self-controlled are considered major assets as they promote interdependence. Traditional Japanese culture, for example, views newborns as independent and making them dependent, bound to and part of the group, is considered a fundamental task of the family. The Japanese traditional practice of keeping young children close to the mother, including the practice of co-sleeping well into childhood, fosters a high level of social and personal closeness, interdependence, and other characteristics that are very different from American culture (19,38,111,112).

Preschoolers

Preschool Chinese children are expected to pay close attention during lessons, unlike American preschoolers. Chinese nursery school teachers initiate and organize most of the daily activities, while the children listen, follow directions, take turns, and share. The activity structure teaches the children the value of self-control, obedience, and cooperation with other children. In contrast, the American nursery school provides a wide range of toys that can be used by children in their own way in free play, transmitting the importance of self-expression and individuality in the American culture (19,38).

Children's inclination to compete or cooperate emerges as a signification differential point among Anglo-American and many non-Western or nonindustrialized cultures. Madsen used a cooperation game for two players, where only one child could partially win if s/he cooperated with the other person but both children lost if they competed. Madsen (34,40) found dramatic behavioral differences between urban Anglo-American and rural Mexican children. The Anglo-American children, particularly the older ones, were far more competitive even when it did not benefit them. The rural Mexican children were far more cooperative, even when they did not directly benefit. The strategies of both groups of children were adaptive within their culture (19).

Culture and School Achievement

Daily experiences of Japanese and many Asian children convey the high level of cultural value placed on formal education, which explains the much higher score of

Japanese students on math and science in comparison to American students. Starting in elementary school, Japanese students spend many more hours in the classroom and doing homework than American students. They also receive extensive tutoring after hours for exams, and enrichment courses (19,38,40). The emphasis of Japanese parents on education reflects their cultural belief that achievement depends on effort; parents are rarely satisfied with their children's academic achievement and urge them to work harder. Until recently, many American parents have believed that academic success depends primarily on innate ability and assumed their children are doing their best (19). Recent research by Carol Dweck, Angela Duckworth, and others has highlighted the importance for teachers and parents to praise both effort and results of their students and children, and to cultivate a perseverance toward long-term goals. A *growth mindset* comes from the belief that one's basic qualities are things that can be cultivated through effort. And, although aptitude, talents, interests, or temperaments may differ, change and growth are possible through application, experience, and *grit* (113,114).

Transition to school is frequently difficult for children from a cultural subgroup attending a school representing the radically different social interactional pattern of the majority culture. Middle-class American children enter school already feeling very familiar and at ease with being asked many questions, particularly *test-type questions* with the answers already known by the adults. African-American children from a lower socioeconomic class were usually unfamiliar with this type of questions and more accustomed to *story-starter* or *accusation* or *analogy type questions* and acted unresponsively to the test-type questions (19,42). The same cultural mismatch between children's usual style of interacting with adults and the expected social style in school has been described with other minority groups, including Native American children and East Indian children in England. This cultural mismatch makes the transition to school more difficult for children from cultural subgroups. It interferes with the shift to decontextualized thought, learning to solve problems that are abstract, and removed from the immediate context by applying their informal problem-solving skills learned at home in everyday life (19,42). It can affect how much children can learn from their school experience and may help to explain the lower average achievement test scores for African-American and Latino children and their higher rate of school dropout and school failure in comparison to Anglo-Americans (43).

Cultural Bias in Testing Intelligence

Any test to measure intelligence (IQ test) is a product of a certain culture, and the level of knowledge of that culture affects how well one performs on that test. There are subtle ways in which cultural background can influence test scores. Cultures vary in their definition of intelligence and the preferred way of performing a cognitive task (44). The interpersonal setting and the racial or ethnic identity of the tester can

reduce the accuracy of test results; children feel more comfortable being tested by members of their own ethnic group. Some children from cultural subgroups feel confused by an adult asking a series of questions when he already knows the answers to them.

To reduce the problem of cultural bias, *culture-free tests* (no culture-based content) and *culture-fair tests* have been developed. In one such test, the problems are presented visually to eliminate the use of language. However, the difference in performance scores on these tests for some cultural groups were unreliably high (44,45). Culture-fair IQ tests uses items that are appropriate to all cultures, but the problem of accurate assessment has remained unsolved. Therefore, intelligence tests remain an effective tool for comparison of intellectual ability within the same culture, but not for comparison across cultures (19).

Cross-Cultural Studies of Adolescence

Adolescence marks the transition from childhood to adult roles in different cultures and has been studied by multiple investigators since the initial observations of Margaret Mead in Samoa in the 1920s. The complexities of adult roles in Western industrialized societies require a very protracted period of learning to acquire the social and technical skills necessary to assume adult roles and gain privileges such as driving (in most states at age 16), voting (18), and drinking (21). Adolescents have to be dependent on their parents financially for a protracted period of time and feel as "marginal" people in a no-man's-land (46), denied full adult social and sexual roles (19). The inner feeling of frustration can lead to a period of conflictual relationship with parents.

In contrast to the experience of adolescents in industrialized societies, anthropologist Margaret Mead found the adolescent transition to adult roles in Samoan culture to be nonstressful and gradual; the adolescent's interests and activities matured progressively and without significant stress or conflicts (4). Her basic conclusions in this area have been supported by subsequent investigations (19).

In some cultures, such as certain tribes in Kenya, transition to adulthood is somewhat abrupt as the growing children's duties expand over a short period of time (19,35,46). Such societies have special ceremonies called "rites of passage" to mark entry into adult roles, which are anticipated by the children for years in advance (19).

The universally accepted dual developmental tasks of adolescence, namely preparation for adulthood and identity formation, follows differential patterns in different cultures. Western cultures tend to encourage achievement through academic endeavors and physical sports. In Confucian-influenced Asian cultures, emphasis is on self-discipline, subjugation of desires and self-refinement as the preferred methods of accomplishment of inner peace (46). Canino and Canino (47) point out that assertiveness, competitiveness, and independence, which are highly valued in Western culture, can be contradictory, for example, to core Puerto Rican values and

may create conflict in Puerto Rican families who live in the mainland United States.

Puberty has been studied extensively cross-culturally. The major noticeable changes of puberty occur over a time span of 4 years and in girls between the ages 9 to 16. Girls in industrialized countries tend to reach menarche earlier than girls in nonindustrialized and developing countries because malnutrition and chronic illnesses are more common. The median age for menarche in North America, Japan, and Western Europe is 12.5 to 13.5, in contrast to Africa, where it is 14 to 17 years. Across a wide range of cultures and countries, girls from higher-income families with adequate nutrition reach menarche sooner than girls from lower-income families. There is no cross-cultural difference in the age of onset of menarche between girls in groups from comparable income families (19,48).

Multiculturalism in Clinical Care

Multiculturalism is based on the assumption that no single way exists to conceptualize human behavior or explain the realities and experiences of diverse cultural groups (89,92,115). In this framework, clinicians are asked to reflect on the observation that each individual has a unique story and that cultural meaning is woven into that story, and into each person, like a tapestry (88,93). Indeed, in every encounter with a patient, there are at least three separate cultures present and interacting: that of the patient and family, that of the provider, and that of the medical or institutional culture where the clinical work is occurring. In this tripartite model, proposed by Tseng and Streltzer (92), it becomes clear that every patient encounter involves mediating effectively ("cultural effectiveness") in relation to each cultural contribution that shapes the interaction (115).

One culture participating in the interaction is that of the patient. Patients come to the encounter with culturally shaped biases, assumptions, and beliefs that are not always known to the provider, but can influence the expectations and desired outcomes. The ethical principle of *Respect for Persons* is fulfilled when providers can effectively work with patients and families with cultural backgrounds different from the provider's (93). The patient's expectations of the psychiatrist, motivation for treatment, explanation for the emergence of symptoms, and adherence with treatment recommendations can all be influenced by the patient's cultural background (115).

The second culture to consider in this exchange is the culture of the health care provider. The social and demographic background, life experience, personal beliefs, and professional training of the provider will shape the interaction and communication with patients. Even when many aspects of the cultural background of the patient and family are similar to those of the clinician, differences are inevitable—and should be welcomed (115).

The culture of American medicine, and its expression in the clinical care

institution, is the third factor in each doctor–patient interaction. Most physicians and other providers within an institution may become accustomed to both visible and invisible elements of the cultural environment of their workplace, and may be unaware of its collective influence on their practice (94). Child and adolescent psychiatry, furthermore, has its own subcultures that include traditions, regulations, and attitudes, not necessitated by specific psychiatric knowledge. For example, whether psychiatrist, nurse, and care manager work together as equal team members or in more hierarchical fashion depends on the past professional and training experiences of each member, as well as the cultural milieu and other influences in the clinical and societal setting. How patients and allied health personnel regard psychiatrists may vary by the dominant culture in that environment (115).

Given that many thousands of health care interactions occur each day and that each is affected by the culture of the patient, the psychiatrist, and the immediate context, the effectiveness of clinical care—as well as the ethics of clinical care—will be influenced by attentiveness to multiculturalism. Stated more negatively, failure to appreciate the impact of culture may render useless or inaccessible what would otherwise be excellent care resources. For instance, persons from other backgrounds may approach the American health care system differently than do persons who are well aligned with Western culture and may encounter significant barriers to care. Language differences serve as one example, but other less obvious barriers also exist related to lack of transportation, limited resources, inability to access and navigate health systems, and limited feelings of trust in health care institutions in the United States, based on prior life experiences (115).

Cross-cultural psychiatric evaluation and treatment describe the skills required to provide care across cultural and linguistic barriers when a clinician consults with a patient from a different cultural/ethnic group who holds a different system of belief values and may speak a different language. In addition to the goal of conducting a comprehensive clinical evaluation, the clinician should assess the contributions of culturally derived forces and stressors to the patient's symptomatology and the adequacy of protective factors in the patient's social environment to mediate stress and promote healthy adjustment. Training programs in child and adolescent psychiatry now have multiple resources, including model curricula and practice parameters which they can draw from when trying to incorporate organized didactic and scholarly experiences in cultural psychiatry (105,106).

Religion, faith, and healing are often so intertwined that in certain cultures, when a psychiatric condition occurs, diagnosis and remedy may be more influenced by spiritual rather than medical interpretation. For example, in Hispanic cultures there is a condition called *susto,* which describes a type of terror or fright that occurs consequent to some trauma. The victim of *susto* or trauma suffers a "soul loss" through fright. As in posttraumatic stress disorder (PTSD), the trauma can manifest clinically as anxiety, panic, fear, or depression. The cure consists of the intervention

of a person skilled in healing—a *curandero,* or healer, who allows the patient to release fears and hostilities (17,49). Treatment consists of medicine, some ritual or ceremony with friends and relatives, and the support of a network of friends. Ultimately, the person is "reassured" through a type of transferential cure—a combined systemic approach that includes a spiritual orientation, the support of friends and family, and faith in the healer.

The evaluator should have an adequate understanding of the patient's culture of origin and the impact of the cultural—or immigration—issues on the child's developmental process. He should inquire about the expectations of parents from the psychiatric treatment, based on their culture of origin. Many immigrant patients may have initially tried folk healers, exorcists, and herbal medicine, prior to evaluation. Such efforts should be explored respectfully and with an accepting attitude. Many families only come for psychiatric evaluation under pressure from school, social agencies, or family court, and their ambivalence about treatment should also be respected (17,46,47). Frequently, there is a profound feeling of failure and alienation in the family because they have attempted unsuccessfully to solve the problem on their own for a prolonged period of time. The pain of the family should be acknowledged empathically, while countering their feelings of being a failure as a family; one should also disavow the family's view of themselves as a "mental illness family" rather than a family with a problem who are actively attempting to find a solution (46,47). The impact of the child's emotional disorder on the internal family environment, interpersonal dynamics, and weakening of the parental authority should be explored. The initial evaluative session serves the multiple tasks of forging a relationship with all family members, collecting data, and enlisting their active partnership in the treatment process. It requires continuous respect and empathy, particularly around inquiries into the parents' explanation for the child's behavior, and addressing their questions and fears. Clinicians can often perform these tasks more comfortably in separate sessions with parents and children. However, clinicians who are proficient in family and individual therapy can effectively accomplish these goals in child-centered conjoint family sessions.

Contrary to the initial view of many clinicians, the contemporary field of cultural psychiatry considers that comprehensive and meaningful evaluations across cultural boundaries can be performed by clinicians who are from a background radically different from a patient's culture as long as the principles and guideline outlined in this chapter are applied.

Clinical Interview

Interviews across the cultural barrier require a high level of attention and sensitivity to the establishment of rapport and empathy with the patient and the family. Respect and deference to elders and head of households can facilitate acceptance by patients

and families. Comments on positive assets of family members, such as children's good manners, can enhance the sense of pride in all family members. The clinician should adopt the preferred communication style of the family; the patient may feel more comfortable with a formal conversational method of inquiry rather than an informal one, or with asking rapid-fire questions from a checklist. Some patients, particularly from more impacted families, should be allowed extra time initially to describe the symptoms in great detail; every daily call from the school about the child's disruptiveness; the child's poor eating habits; irregular sleeping routine; disrespect for the parents. This communication style should only be redirected in a way that avoids alienating the person. Certain content may carry stigma, such as discussion of overt aggression, suicidality, or sexuality with certain cultural groups. The patient's preference should be respected and handled with special tact, as if one were conducting a complex defense/resistance analysis.

Language proficiency as a barrier to health care is a formidable obstacle to the care of several cultural groups, particularly with the increasing number of immigrants in the United States. It is estimated that up to 50% of some cultural groups are monolingual and the level of language proficiency and language independence of many patients in the remaining half may fall short of what is needed for an accurate and comprehensive psychiatric assessment. Therefore, a variety of interpreters, specially trained translators, and cultural/linguistic consultants are engaged to facilitate the communication process between the clinician and the patient. The highest level of assistance can be rendered by cultural/linguistic consultants, who work closely with members of the clinical team, and are especially trained and sensitized to recognize rich affective and cognitive context accompanying the patient's verbal communication in order to arrive at the *connotative meaning* of their expressions, rather than just the literal ones. There are guidelines for the use of interpreters, using the necessary translation time to make additional observations about the patient's behavior, and also to recognize errors in translation based on a patient's response. Frequently, patients can recognize intuitively the translation errors of the interpreter and they should be empowered to point them out. The evaluator should have the necessary skills to recognize the patient/translator "transference," translator-patient "countertransference," and ways of avoiding splitting the authority (transference) between the translator and the clinician. Many fully bilingual patients—particularly Latinos—may choose to use an interpreter in the sessions in order to focus their efforts on describing their situation. They frequently correct the interpreter during translation errors. This phenomenon should not be misunderstood as a power-struggle maneuver, but as a preferred communication style. Furthermore, the language proficiency of a fully bilingual person can fall short during the description of traumatic events from the past that are laden with intense affect (50–53).

Cultural Formulation

Cultural formulation is a key concept in the biopsychosocial assessment and diagnosis of mental disorders, similar to psychodynamic or biologic formulations. The DSM-5 recommends inclusion of a number of components into such a formulation to make it serve as a sensitive instrument to address the requirements of a comprehensive assessment in culturally diverse or multicultural groups (1,53). The formulation should include (a) the cultural identity of the patient; (b) cultural explanations of the patient's illness; (c) cultural factors related to the psychosocial environment; (d) cultural elements of the physician–patient relationship; and (e) overall cultural assessment for diagnosis and treatment. Specific adaptations in the cultural formulation relevant to child and adolescent psychiatry are presented in a useful review by Aggarwal (95).

For immigrants, cultural formulations should include pre-immigration history, including educational or employment opportunities, as well as major conflicts, losses, or traumas that may have contributed to the immigration. For example, a 13-year-old girl who lived with her grandmother in Puerto Rico for most of her life was sent to the United States abruptly after she was severely abused by a relative. The trauma of the abuse, the abrupt loss of the relationship with her primary psychological caregiver, and the unpreparedness of the mother to care for the daughter after many years of separation were not included in the formulation. The American Psychiatric Association has now published highly practical guidelines for conducting interviews with diverse groups of patients and families. The Cultural Formulation Interview, CFI, is adapted for children, immigrants, the elderly, and other specific populations (96).

Mental Health and Psychiatric Care: Effect of Culture in Help-Seeking

Needs assessment surveys of the general population have consistently shown that most people with serious emotional problems do not seek professional help, particularly from mental health professionals. With a culturally diverse population, unique and powerful barriers are operative, which may explain the low level of utilization of mental health services by minorities and culturally diverse groups, as emphasized in the 2000 Surgeon General's report (54). Chief among them is fear of stigmatization and discrimination, which combines with attitudinal, demographic, and system-dependent factors.

The fear of discrimination, particularly due to linguistic barriers, is a formidable deterrent for many members of certain cultural groups. Equally significant is the fear of disregard, disrespect, or misunderstanding the patient's culture and customs. Fear of disregard for the status of parents and elders, and the importance of the children's

respect for parents, parental values, and loyalty to the family keep many families from seeking help. Essential clinician variables are empathy, skillful perceptiveness, effective communication, straightforwardness, honesty, flexibility, intellectual curiosity, open mindedness, and tolerance for psychological challenges of adolescents and children (55,56). Adequate inquiry into parental views of the problems, their explanation for the behavior, their expectations of treatment outcome, keeping them informed of the treatment progress, and addressing crisis situations by involving the family can help forge a strong therapeutic alliance with the family. Rogler and colleagues (16) recommend the following requirements for providing mental health services to culturally diverse populations: (1) locating mental health services in minority neighborhoods and close to public transportation, as minority groups tend to congregate closely to each other; (2) employing mental health workers and clinicians who share the linguistic and cultural backgrounds of the patients; and (3) creating an ambiance that reflects the cultural heritage of the patient population in outpatient and hospital settings.

Culturally specific therapies are increasingly emerging in the clinical research literature and incorporate specific elements from the patient's native culture into therapeutic interventions (1). Such approaches modify conventional psychiatric treatments by incorporating folk rituals, herbs, and the patient's own cultural conception of the illness into therapeutic interventions.

A large number of patients in the majority culture tend to seek treatment for their emotional disorders from a primary care physician. In a seemingly parallel phenomenon, many members of minority groups tend to seek treatment relief and support from outside the mental health system from people such as a *curandero* and folk healers in Latino cultures. Mental health programs can penetrate the lay referral structure by assembling some credible members of the ethnic network into their professional structure (46,47). Informal and immediate registration of the patient for the initial contact with treatment can reduce the barrier to care (46,47,57).

The Social and Cultural Context of Psychopharmacology

As Lin and colleagues (97) have described, "pharmacotherapy is fundamentally a process of social transaction, and its outcome is determined by contextual factors impinging on the patient, [family], and the clinician by forces that powerfully shape their interactions." Furthermore, these investigators highlight the need for clinicians to acknowledge "that [they] are just as malleable, consciously and unconsciously, by their sociocultural environment and prevailing ideologies." They invite us to struggle against certain prevailing notions of modern pharmacotherapy, which can undermine effectiveness. These notions include that (1) the therapeutic effects of medications are determined exclusively by their biologic properties (2); the patient is a passive recipient of the prescription, and will be fully adherent with instructions; and (3)

psychiatric and medical treatment represents (or is supposed to be) the only source of care available and used by the patient (97). Culture influences the same areas that are central to mental health, such as behavioral expectations and tolerance, language, emotion, attention, attachment, traumatic experiences, conduct, personality, motivation, limit setting, and other aspects of parenting in general. Cultural context plays an important role not only in structuring the environment in which children with emotional and behavioral disorders function, but also in the way such children are understood and treated (104).

Shame can be another cultural paradigm that enters the clinical setting (104). For both parent and (especially teenaged) patient, the stigma of mental illness may be further fed by being referred to the psychiatrist by the primary care provider (PCP). From the family/patient perspective, the implication is that the problems are so serious, too threatening, or so time consuming as to require a specialist, beyond what the PCP (who is often a trusted adult in the teen/child's life) can handle. Metzl (98) has described how clinicians should strive to promote an "open and honest exchange of affect," especially because patients and families are often "sent" to our offices "to relate deep and highly personal aspects of their lives to a total stranger" (p. 39). Broucek and Ricci (99) encourage us to "reduce the patient [and family's] shame and anxiety to levels more conducive to self-revelation. Intense shame [particularly among parents of some cultures] can be so aversive, noxious, and self-fragmenting that the [pharmacotherapist] may have to assist [them] in modulating it" (104, p. 435).

Another influential piece of writing comes from Havens (100,101), who describes the use of "psychological analgesics," which can be prescribed in much the same way as our medical predecessors may have told the patient to "take 2 aspirin and call me in the morning":

1. Protect self-esteem: the patient has been potentially affected by having to come to a psychiatrist, and the parent may feel guilty for having caused the illness through bad parenting, poor gene contribution, or both.
2. Emote a measure of understanding and acceptance: when this technique is successful, the patient's problem is grasped intellectually, and the patient's and family's predicament is understood from *their* point of view.
3. Provide a sense of future: many families have experienced frustration and failure in attempting to find solutions and may have lost hope. Discussion about and expectations for treatment that still acknowledges fears or even hopelessness may still preserve opportunities for change: "It may seem hopeless to you *for now*."

Sabo and Rand (102) emphasize the importance of spending adequate time with the patient (and family) in the initial evaluation. Patients too often feel as though they are merely "the next appointment" unless the doctor listens to the personal and unique elements of their story. Interpreters in the initial appointment can be crucial at this

stage in the treatment relationship. Active empathic listening is necessary to create a special, common language between the patient and therapist. If a full workup cannot be completed in the first appointment, follow-up sessions (preferably within 1 to 2 weeks) may be necessary to sustain the developing alliance. This situation becomes especially true with those families sufficiently unfamiliar with mental health disorders and their treatment that they may be unsure of what to expect in terms of treatment planning and treatment response. In families from cultures in which somatization is a frequent way to present mental health symptoms, the attuned pharmacotherapist finds ways to selectively use the medical model or chemical imbalance explanation to gain buy-in, but may also use the opportunity to help families conceptualize how mental health problems can greatly impair daily function (e.g., school performance, peer and family relationships, self-worth). Choi (103) writes how "becoming familiar with the language for emotional distress and understanding cultural beliefs embedded in [certain cultural or culture-bound] expressions are critical steps for culturally competent communication between [clinicians] and adolescents" (104, p. 79).

Some cultural groups may hold a culturally shared belief that emotional disorders are somatically based and best treated with medication; they expect a rapid rate of recovery from target symptoms and are alarmed by side effects that they relate to "toxicity." Specific Asian groups, such as those of Chinese, Korean, and Japanese heritage, may require much lower medication doses, at times one-half or one-third of the conventional doses, to achieve therapeutic response (1,46). Therefore, cross-ethnic variations in drug responses ought to be a clinical focus.

Cytochrome P450 isoenzymes are key in the metabolism of psychotropic and nonpsychotropic drugs. The genetic anomalies in "poor metabolizers" are unequally distributed among ethnic populations. The percentage of CYP2D6 poor metabolizers is lower in Asians and higher in Caucasians. Similar interethnic variance exists in frequency of poor metabolizers of CYP2Cmp; low among whites (3%), intermediate for African Americans (18%), and higher in Asians (up to 20%). Immigrants and members of many subcultural groups commonly use herbal medicines. Inquiry into the use of the traditional herbal medicines of Asians, Latinos, and other immigrants to the United States is essential because many of these herbs possess psychoactive activities. Others such as ginseng may stimulate or inhibit cytochrome P450 enzymes (1,46).

The American Multicultural Society

At the start of the 21st century, American society and the global community have become increasingly heterogeneous with respect to racial, ethnic, and cultural composition. Global demographic trends reveal a world in which the majority is characterized by cultural heterogeneity rather than "ethnic purity." For the first time,

the majority of the parents in the United States are raising their children in cultural settings other than those where they themselves were raised (57). The diverse profile of American and global families has given rise to the theoretical orientation of multiculturalism. Multiculturalism is based on the assumption that there is not a single way to conceptualize human behavior and to explain the realities and experiences of diverse cultural groups, and that no particular set of competencies have proven effective with every form of diversity (57,58,61).

Models of Culturally Informed Care

Multiple models have been proposed to guide clinicians in their professional roles. Here we adapt previously published work (115) and briefly discuss four models: the Cultural Competence Model (116), the Explanatory Models Approach (117), the LEARN Model (118), and the Culturally Competent Communications Model (119). All of these models highlight the role of culture in communication with patients and families, and focus on the development of treatment approaches that are respectful, helpful, and which avoid harm.

The Cultural Competence Model

Terry Cross and his colleagues introduced the term "Cultural Competence" in the 1980s to address the cultural needs of a growing population of diverse children and youth with serious emotional problems (116). They defined cultural competence as the state of being capable to serve people from diverse cultural and socioeconomic backgrounds. They outlined components of the knowledge, skill, attitudes, and values that both clinicians and their health care organizations should incorporate in order to operate effectively in a context of cultural difference.

While acknowledging that the concept of "cultural competence" may appeal to educators, some scholars point out that this term denotes a sort of end point, and that this "mastery of a body of knowledge and skills may insidiously lead us down the wrong path when applied to cross-cultural interactions. Culture is not a finite data set to be mastered, but instead a concept that is complex, dynamic and individual" (120).

Although our shared medical culture is based largely on achieving competence, we should take care when applying this term broadly to *mastering* other cultures (emphasis added). We may find that competency-based education can be applied more easily to the domains of knowledge and skills than to attitudes. Communication skills built upon the attitudes of openness, flexibility, self-reflection, and, yes, *humility* are ultimately what will make individuals responsive and sensitive to the delivery of care to diverse populations. This is the framework medical educators should be striving to introduce, model reinforce, and evaluate. This is the path of lifelong learning about oneself in relation to others that is most fruitful (120).

The term "cultural humility" (121,122) is consistent with the concepts of self-reflection and self-critique, instead of mastery of sets of information. The physician who can be responsive and attuned to cultural nuances and differences is most likely to incorporate information provided by patients and families, and is less likely to leave sociocultural misunderstandings unaddressed. In this way, the physician can emote an understanding of the patient's/family's situation from *their* point of view. Other authors caution against defining "culture" too narrowly (123).

The somewhat abstract nature of the term *culture* often results in a workplace definition of culture that is narrow and concrete, and may reduce culture to ethnic minorities (only). This type of thinking often leads to exempting providers from ethnic minority backgrounds from the responsibility of providing culturally competent care. It further leads to ignoring the need to provide culturally competent care to all groups, such as White men. Such a restricted notion of culture also fails to address the complexities in the relationships between an individual, his or her culture, and the culture of biomedicine, which is alien to most patients (p. 174).

The above models highlight that culturally informed approaches to medical care feature basic patient/provider communication skills that focus on a patient- and family-centered approach, openness to the experience of the other, flexibility, and self-reflection on the part of the provider.

The Explanatory Models Approach

In the field of anthropology, culture is seen as neither homogenous nor static (121,123). Culture is made up of multiple variables, affecting all aspects of experience. Medical anthropologist, Arthur Kleinman (117), states that culture "is inseparable from economic, political, religious, psychological and biological conditions. Culture is a process through which ordinary activities and conditions take on an emotional tone and a moral meaning for participants … Cultural processes frequently differ within the same ethnic or social group because of differences in age cohort, gender, political association, class, religion, ethnicity, and even personality." The shortcoming is that the medical field often falls into a categorical trap, and may *equate* culture with ethnicity, nationality and/or language. An example would be to assume that patients of a certain ethnicity are assumed to have a core set of beliefs about illness owing to ethnic traits.

Cultural "competency" (then) becomes a series of "do's and don't's" that define how to treat a patient of a given ethnic background. The idea of isolated societies with shared cultural meanings would be rejected by anthropologists today, since it leads to dangerous stereotyping—such as, "Chinese believe this, "Japanese believe that," and so on—as if entire societies or ethnic groups could be described by these simple slogans (p. 1673).

Kleinman introduced the Explanatory Models Approach as an interview technique that seeks to clarify how the social world affects and is affected by illness within the

context of an individual's life. The aim of this approach is to more fully open clinicians to human communication and set their expert knowledge *alongside* the patient's own explanation and viewpoint.

The explanatory models approach does not ask, for example, "What do Mexicans call this problem?" It asks, "What do you call this problem?" and thus a direct and immediate appeal is made to the patient as an individual, not as a representative of a group … The one activity that even the busiest clinician should be able to find time to do is to routinely ask patients (and where appropriate, family members) what matters most to them in the experience of illness and treatment. The clinicians can then use that crucial information in thinking through treatment decisions and negotiating with patients (p. 1673).

This approach expands upon the DSM Cultural Formulation and allows clinicians to create a short ethnography-like formulation. "Ethnography" is a term from the field of anthropology that refers to the description of what life is like in the "local world" of the person (patient)—usually one different from the anthropologist's (physician's). It facilitates empathy with the patient/family's lived experience of the illness, and can lead to a narrative that ideally *conveys the clinical story* from the patient/family's worldview. The six steps in this ethnographic approach include (1): Asking about ethnic identity and whether it matters for the patient—e.g., whether it is an important part of the patient's sense of self (2); evaluating what is at stake for the patient/family and their loved ones. This can include inquiring about close relationships, financial/material resources, and religious/spiritual beliefs. It can shed light on the moral lives of patients/families (3); constructing the "illness narrative," based on a series of questions (Box 2.2.1.1) to understand the meaning of illness. Explanatory models can be used to open up a conversation on cultural meanings that have clinical relevance (4); considering the current stressors and social supports in patients/families' lives (5); examining the influence of culture on the clinical relationship. An important ethnographic tool is self-reflection regarding the intersection of the world of the physician and the world of the patient. Kleinman reminds us that "teaching practitioners to consider the effects of the culture of biomedicine is contrary to the view of the expert as authority and to the media's view that technical expertise is always the best answer" (117), and (6) considering how relevant cultural issues are to a particular clinical situation. This important sixth step asks whether too much attention to potential cultural differences with the provider could be experienced by the patients and families as intrusive, and could even lead to a sense of being singled out and stigmatized, or lead to a misdiagnosis (124–126).

BOX 2.2.1.1

THE EXPLANATORY MODELS APPROACH

What do you call this problem?

What do you believe is the cause of this problem?
What course do you expect it to take? How serious is it?
What do you think this problem does inside your body? How does it affect your body and your mind?
What do you most fear about this condition?
What do you most fear about the treatment?

(Kleinman A: *Rethinking Psychiatry: From Cultural Category to Personal Experience*. New York, The Free Press, 1988.)

Another often-used model comes from the Family Practice literature, using the acronym *LEARN* (118). The authors created a process-oriented model by which cultural, social, and personal information relevant to a given illness episode could be elicited, discussed, and negotiated or incorporated (Box 2.2.1.2).

Teal and Street (119) have proposed that applying the cultural competency model to the medical encounter requires attention to the specific characteristics and circumstances of the individual patient and family (Fig. 2.2.1.1). The approach includes key communication skills such as the incorporation of cultural knowledge, recognition of potential differences, verbal and nonverbal behaviors, and negotiation and collaboration. These elements are seen as fundamental to acquisition of more skills and corresponds to increasing complexity and culturally competent communication.

BOX 2.2.1.2

THE LEARN MODEL OF CROSS-CULTURAL COMMUNICATION

L*isten* with empathy to the patient's perception of the problem
E*xplain* your perception of the problem
A*cknowledge* and discuss both differences and similarities
Recommend treatment
Negotiate agreement

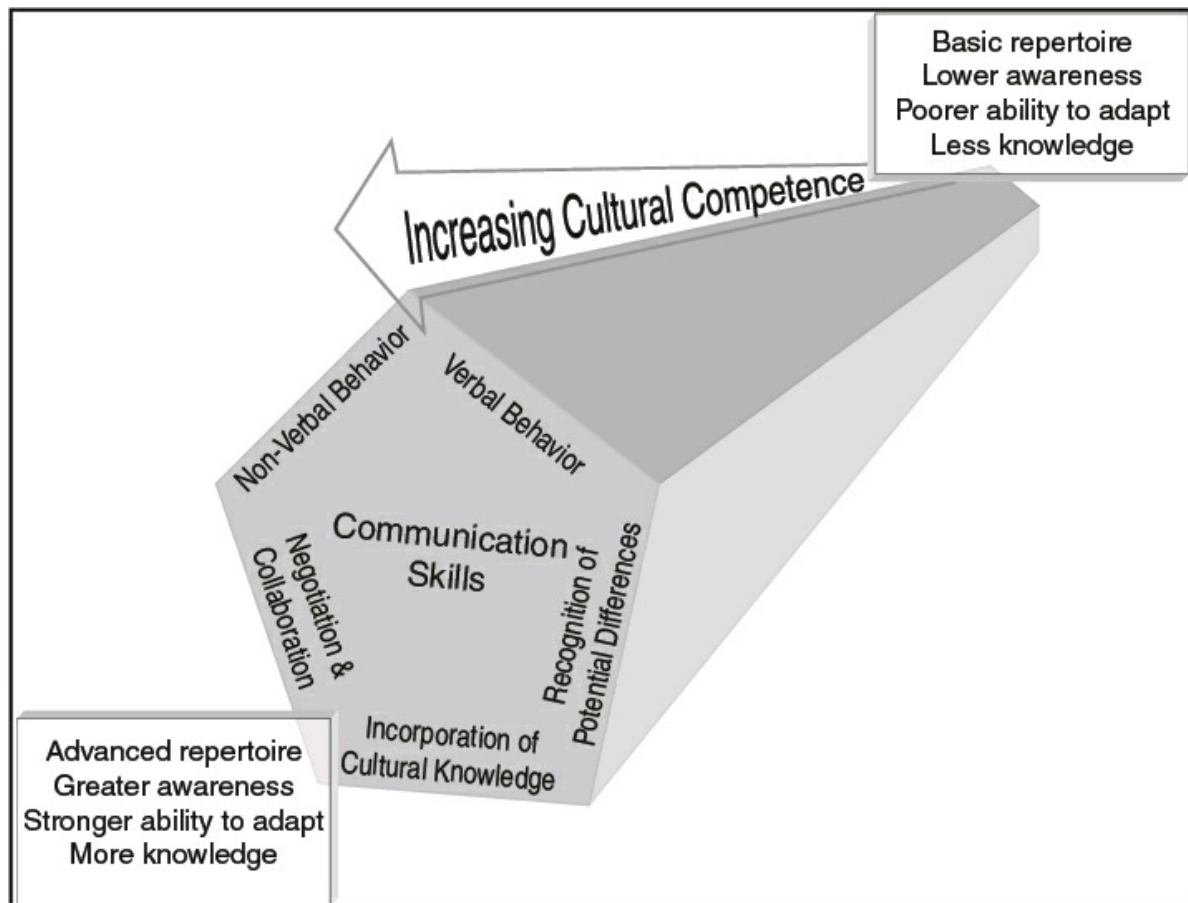
(Adapted from Berlin EA, Fowkes WC: A teaching framework for cross-cultural health care: application in family practice. *West J Med* 139:934–938, 1983.)


FIGURE 2.2.1.1. The Culturally Competent Communication Model. Reprinted, with permission, from Teal and Street (2009).

The culturally competent communication model integrates existing frameworks for cultural competence and explanatory models including culture in patient care, with models of effective patient-centered communication. In this model, there are four critical elements of culturally competent communication in the medical encounter: communication repertoire, situational awareness, adaptability, and acknowledging core cultural issues.

In clinical situations where cultural elements present themselves as important elements of clinical care, it may be useful to consider obtaining a cultural consultation, where important insight and understanding may be gained by learning about the culture and history of a specific group. Discussion with a cultural broker to gain insight into a case where a cultural issue has the practitioner frustrated is very appropriate, and possibly essential. Furthermore, insights into that culture's model for disease and their perception of effective treatment may help clinicians to be more effective in understanding the perspective of their patients and families, and discussing treatment plans. Consultation on cultural issues may be considered similar to consulting with a health care colleague with a different specialty. Similarly, if a health care provider is working with many patients with a common experience, the provider can improve effectiveness by learning more about the realities and/or risks associated with that particular issue. For example, providers working with refugee

patients would benefit greatly by learning about the experience of refugees, the common psychosocial circumstances refugees face, and the increased risks for adverse experiences and illness they have because of their experience (115).

CONCLUSIONS

Cultural child and adolescent psychiatry describes the body of theoretical and technical knowledge necessary for clinicians to provide competent psychiatric care across cultural and language barriers to children, adolescents, and families. It is based on the theoretical orientation of multiculturalism, which assumes that there are multiple ways to conceptualize human behavior and explain the realities and experience of various forms of cultural diversity, and that no particular set of competencies have proven effective in all cultural settings. The cultural relativist perspective asserts that cultural values and meanings are relative to and embedded in their cultural context, and cannot be measured against a universal system. It uses locally meaningful observations to examine the impact of cultural context on the developmental processes in children and their ultimate personality characteristics.

The increasingly multicultural American and global communities have acted as a compelling force for the growth of the field of cultural psychiatry and psychology. The incorporation of a vast body of cultural knowledge into descriptions of developmental processes, psychiatric diagnosis, clinical formulation, and culturally sensitive treatments have necessitated the expansion of our fundamental biopsychosocial model as described by George Engel 50 years ago. That model can be expanded into a *biopsychosociocultural model* to address the complexities of the clinical and developmental processes in a heterogeneous group with respect to their racial, ethnic, and cultural composition. It allows evaluation and description of the experience of individuals from one cultural group with another dominant culture, their acculturation process and tensions, and the opportunities created by their unique differences.

In this chapter, we have avoided organizing the sections into culturally specific categories, as online resources for culture-specific clinical strategies are easily accessible (127–129). Furthermore, while the practice of highlighting specific issues unique to ethnic, linguistic, and racial populations has its place in the medical literature, we agree with previous writers (115,117) that there is greater value in emphasizing more generalizable principles, knowledge, and skills for cultural effectiveness in clinical practice. Although some cultural groups have been highlighted more than others, these are meant to serve as examples of how to conduct culturally sensible practice, rather than to be focused on as broad assumptions about specific patients of a cultural group. We and others (103,105,130) are striving to change the “misguided perspective that the close relationship between culture and illness occurs strictly in the lives of ethnocultural minorities (only).” Rather, we

believe this relationship and these connections are human ones, and occur in persons of all races, ethnicities, and backgrounds.

CHAPTER 2.2.2 ■ PSYCHIATRIC CARE OF THE DEAF, BLIND, OR DEAF-BLIND CHILD

KAREN A. GOLDBERG AND JANA K. DREYZEHNER

GENERAL CONSIDERATIONS

This chapter provides an overview of deafness and visual impairment conditions, which alone or in combination with other medical challenges, can have a significant impact on a child's development and mental well-being. Sensory-related loss does not cause psychiatric illness per se but may affect symptom presentation. Misdiagnosis of psychiatric disorders may occur if the diagnostician is unaware of the adaptive differences and, hence, the variability in timing and acquisition of developmental milestones. Misdiagnosis may also occur if the practitioner does not appreciate the impacts of communication challenges the deaf or blind child has with primary caregivers. The child's environment can shape the sequential acquisition of skills and the developmental process. Troubled behavior may represent independent psychiatric conditions or consist of acquired maladaptive compensatory behaviors. The influence of deafness or blindness on the developmental process as well as the presentation of psychiatric signs and symptoms and the context in which the child functions are pivotal to the psychiatric evaluation of the child with hearing loss or blindness.

The objectives of a psychiatric evaluation are accurate diagnosis and development of an appropriate treatment plan that addresses the multiple and complex problems identified (1). The nature and extent of impairments differ with etiology, age of onset, and other complicating factors. Fundamental considerations for evaluation of a deaf and/or blind child include:

a. The tremendous range and heterogeneity of the sensory loss;
b. Occurrence of multiple sensory losses (e.g., Deaf-blind conditions);
c. Co-occurring challenges (autism, intellectual disability);
d. Complex interdependence of the sensory-related issue with environment;
e. Caregiver response to having a deaf or blind child;
f. Differing potentials among children with similar sensory loss.

Comorbidities may occur from autism spectrum disorders, attention deficit hyperactivity disorder (ADHD), intellectual disabilities, neuropsychological disorders of learning, central nervous system syndromes, and traumatic brain injuries. Many children and adolescents who have comorbidities often do not fit neatly into a simple DSM-5 diagnosis, and should be categorized through a comprehensive biopsychosocial-developmental evaluation and presented in context of comorbid diagnoses. In addition, those who evaluate and work with youngsters

who have degrees of deafness and blindness may lack awareness and understanding that many individuals with sensory-related losses with or without comorbidities lead successful and constructive lives. This point is important because professional attitudes and expectations can dramatically shape the evaluation and treatment outcomes.

Being a deaf, blind, or deaf-blind individual does not necessarily increase the risk of developing mental health problems. However, associated factors and presence of additional medical problems may increase the likelihood of mental health issues. Consequences of being deaf or visually impaired in a world that is oriented to the needs of hearing and sighted people may add to the burden of these individuals. The vast majority of deaf and visually impaired children are born into hearing and sighted families, and as such, it is important to consider the goodness of fit in meeting the needs of the child. Brain insults and other physical illnesses linked to the cause of deafness or blindness may confer additional neuropsychological vulnerabilities. Finally, children with deafness and visual sensory impairments are more vulnerable to all forms of abuse and neglect (2).

MODELS OF DEAFNESS, VISUAL IMPAIRMENT, AND DEAF-BLINDNESS: CULTURE AND DISABILITY

It is important that clinicians understand that there are two key models used in conceptualizing deafness and blindness: the medical model and the cultural model. These models are not necessarily in contrast with one another but may help clinicians in understanding the differing perspectives. Deafness and/or blindness not only affects how the child perceives the world, but how the world perceives the child and most importantly, how the child perceives him/herself.

Medical definitions of deafness and blindness focus on the sensory impairment including the etiology, severity, age of onset, and the presence or absence of additional disabilities. It also focuses on possible medical interventions to aid or correct the defect. The medical model provides a language for practitioners to communicate regarding the actual audiologic/ocular conditions but leaves out consideration of the context and cultural identity of the individual with the hearing or visual impairment. Medically accepted terms include sensory impairment, hearing impairment, hearing loss, and deafness as well as visual impairment, vision loss, and blindness.

Cultural models focus more on the richness and uniqueness of the social experience, as well as the connectedness among members sharing the sensory-related issue and their combined sense of purpose and group identity. The cultural model challenges the notion that deafness or blindness represents solely a sensory-related loss and rejects the notion that the person is disabled, impaired, or needs to be fixed. Deaf culture consists of a set of beliefs, unique language, and proud history shared by

deaf individuals. Deaf with a capital D is used to connote this sense of cultural identity while the smaller case d, deaf, is used to connote the actual audiologic condition. Deaf cultural perspective rejects medical terminology that indicates impairment. Preferred terminology for the hearing loss is deaf, deafness or hard of hearing. Blind individuals and those with visual impairment share unique experiences with one another, but a specific blind culture does not exist per se (3). Individuals who are both deaf and blind often align with Deaf culture and refer to themselves as Deaf-Blind persons. This chapter will attempt to present the material in a manner that is both culturally and linguistically affirmative, and as such, will utilize as much culturally preferred terminology as possible. Table 2.2.2.1 provides useful definitions.

TABLE 2.2.2.1

DEFINITIONS OF DEAFNESS AND BLINDNESS

Deafness	Blindness	Deaf-Blind
SEVERITY: Mild 21–40 dB Moderate 41–70 dB Severe 71–90 dB Profound 91+ dB	SEVERITY: Mild 20/70 or better Moderate 20/70–20/200 Severe 20/200–20/400 Blindness 20/400 or worse Legal blindness: Worse than 20/200	SEVERITY: Deafness + any degree blindness Legally blind + any degree deafness
AGE OF ONSET: Congenital Early onset Acquired/Late deafened Progressive	AGE OF ONSET: Congenital Early onset Acquired	AGE OF ONSET: Congenital Early onset Acquired
SITE: Conductive Sensorineural	SITE: Peripheral Central	SITE: Conductive or sensorineural deafness Peripheral or central blindness
DESCRIPTOR: Deaf: Profound deafness Hard of hearing: Moderate to severe deafness	DESCRIPTOR: Characterized by severity on the Snellen visual acuity test	DESCRIPTOR: Any combination of deafness combined with any degree of visual impairment
CULTURAL: Communication with common language (American Sign Language) Identification and unity with other deaf individuals Common experience of being minority community and history of oppression	CULTURAL: No distinct language apart from majority community Braille is translated majority language (not separate language) Shared experience of experiencing world with visual impairment	CULTURAL: Identify more with Deaf culture Common experience of communication with hand over hand signing or hands on finger spelling. Identification with other deaf-blind people and experience of oppression

The National Standards for Culturally and Linguistically Appropriate Services (National CLAS Standards) in Health and Healthcare were first developed by the Health and Human Services Office of Minority Health in 2000 with the aim of

advancing health equity, improving quality, and helping eliminate health care disparities. It was designed as a blueprint for individuals and health care organizations to implement CLAS. The Enhanced Standards (2013) are a comprehensive series of guidelines that inform, guide, and facilitate practices related to culturally and linguistically appropriate health services (4).

There are several resources that would be useful for practitioners in working with deaf and blind children. The National Association of the Deaf (NAD) is the nation's premier civil rights organization of, by, and for deaf and hard of hearing individuals in the United States of America (www.NAD.org). Alexander Graham Bell Association is another resource for hearing loss with more focus on listening and spoken language (www.AGBELL.org). The American Foundation for the Blind (www.AFB.org) and the National Federation of the Blind (www.NFB.org) are two excellent resources for information regarding vision loss. The Helen Keller National Center for Deaf-Blind Youth and Adults (www.HKNC.org) is an excellent resource as well for the combined conditions.

THE ROLE OF THE CHILD AND ADOLESCENT PSYCHIATRIST

The role of the psychiatrist is unique as liaison to interface and interact with a multidisciplinary medical or rehabilitation team and the family, school, and community. The training of a child and adolescent psychiatrist permits the comprehensive integration of biologic, developmental, family/environmental, learning/educational, and psychodynamic/psychiatric issues in order to develop a diagnostic formulation. In both evaluation and treatment, the consulting psychiatrist needs to establish a collegial relationship with the parents and school staff. Frequently, the school or rehabilitation service requests a consultation in order to assess risk of suicide, psychopharmacologic management, or change in level of care or educational program. Current educational trends for sensory-related issues include early intervention assessments and therapeutic programs for infants and toddlers exhibiting developmental delays and integration of deaf and blind children into regular schools. These trends increase the probability that child psychiatrists lacking specialized experience may be asked to evaluate these youngsters. Referrals may come directly from schools where children are mainstreamed or from specialized schools (schools specific for deaf and/or blind students). In specialized schools, there is a need for initial triage, assessment of complex biopsychosocial issues, and managing the psychiatric care. Most cases of deafness or blindness are lifelong; hence, the initial involvement of the child psychiatrist often evolves into a long-term connection. Child and adolescent psychiatrists must accommodate comfortably to specialized settings and adapt innovative interviewing techniques in both assessment and treatment.

Learning manual sign language is very helpful in working with deaf and hard of hearing children, but difficult to master. A certified interpreter for deaf children and utilization of play with a blind child are feasible alternatives. Familiarity with the use and purpose of various assistive devices can facilitate rapport with the child and family. The child psychiatrist who is best able to approach the evaluation is knowledgeable in child development; looks for adaptational, problem-solving, and functional strengths; is aware that a sensory loss does not routinely result in psychological impairment; and seeks to identify the strengths and weaknesses within the child and his/her family. The questions, "How does the deafness or blindness interface with the developmental process and/or the environment and what have been the adaptive responses?" are very helpful. The goals of the examination should include looking for the child's level of independence, cognitive abilities, functional abilities, communication abilities, social adjustments, and psychological adaptations. Further, the examiner would want to consider why this case has been referred at this time; who made the referral; what is happening in the home, family, or school; for example, does the child need a new school or is the child aging out of the current school; has the child grown and developed to the point where previous management techniques are no longer possible and medications are being requested; and is there an underlying purpose for the referral, such as expediting removal of the child from the home, school, or changing the level of care? Assessment of the various domains of development is indicated in infants and toddlers. Further, the examiner would want to assess the child's ability to understand cause and effect relationships to modify his or her behavior. Reviewing various records and looking for the longitudinal patterns in addition to associated impairments answers some of these questions.

The psychiatrist who is educated about the medical and cultural aspects of the sensory-related condition would be in an ideal position to offer optimal service. The evaluating psychiatrist needs to ascertain the parents' expectations and from what sources they have received advice. The parent may have the view of the deaf or blind child as permanently damaged and this may be a contributor to the psychological distress that the child experiences. Alternatively, the parent may minimize or deny the reality of their child's circumstances, pursuing unrealistic treatments and goals. The level of the parental involvement and advocacy for their child are important predictors of the child's success. In many cases, the "validity" of the parental expectations can be determined only after the fact, retrospectively once the child has grown. Assessment of the environment and family of the deaf or blind child must be an integral component to the comprehensive psychiatric evaluation. The parents or primary caregivers may experience extreme demands on their time and energy in caring for the child, may experience pressure from family or community members on how best to deal with the situation, and may experience periods of emotional distress themselves. These strains could lead to deleterious interactions with the deaf or blind child and may negatively impact the bonding between child and parent. Family

structure and alliances can become skewed, and the full dimensions of family life may be curtailed. Financial costs can further tax family resources. A gulf can grow between parents as polarized reactions occur. Siblings may feel excluded, jealous, or cheated while conflicted with the relief that they themselves are not dealing directly with the sensory-related issue. Many families are able to form healthy and constructive responses. The task of communicating one's findings and engaging the family and school toward recommended treatment and intervention is made more difficult if they have contributed to maladaptive behaviors and stunted development. Clinical sensitivity and expertise is required to help parents and other caregivers including school personnel recognize both their positive and negative influence on the process and outcome of treatment.

DEAF, HARD OF HEARING, AND HEARING LOSS

Definition

Hearing loss in children is divided into hard of hearing and profoundly deaf groups. Historically, the distinction was based on those youngsters who could utilize their diminished auditory perceptions for communication and those who could not. There was early pressure to mold these youngsters into the oral hearing world as much as possible. This drove the development and refinement of hearing-assistive devices such as cochlear implants, digital hearing aids, auditory loops, FM systems, and infrared systems. Early identification and expanded rehabilitation services has permitted an increasing number of children with significant hearing loss to effectively use their residual hearing. Hearing loss in children is also classified by the age of onset. "Prelingual" refers to onset of hearing loss before the use of spoken language, and "postlingual" to hearing loss occurring after spoken language has been acquired. Generally, a loss of hearing before 2 years of age is considered prelingual. The age of onset of hearing loss can have a significant impact on oral language acquisition.

Hearing deprivation has existed throughout history. Educators and religious figures who have taken on the task of instruction of deaf pupils have influenced Western European attitudes and practices. The controversy among proponents of manual, oral, and total communication (combination of both manual and oral language) has waxed and waned over time and are detailed in the *Oxford Handbook of Deaf Studies, Language, and Education*, Volume 2 by Marschark and Spencer (5). The Deaf culture movement has challenged the rights of parents, medical professionals, and educational systems to remove a child from the culture by assistive hearing devices such as cochlear implantation (which is often done by the age of 2 years old). Further, it has questioned the obligation of larger systems and even society's role in pressuring parents, particularly hearing parents, to pursue a means to "cure" deafness rather than present alternative perspectives in managing

deafness (American Sign Language [ASL] and inclusion in Deaf culture). Deaf culture and the promotion of ASL have influenced implementation of the Individuals with Disabilities Education Act (IDEA). With the introduction of Public Law 94-142 in 1975, deaf and hard-of-hearing students have increasingly been taught and educated in regular schools largely populated by hearing children, although the extent of academic integration varies. The IDEA revision of 2004 further supported the movement of deaf and hard-of-hearing students into mainstream education where opportunities for bilingual (sign and oral language) education and an accommodation for various communication devices (language boards, computers, etc.) is an expectation. Public Law 99-457, which established early intervention programs, has done the same for children ages 0 to 3. The recommendations of the Commission on the Education of the Deaf also represent significant steps on behalf of the deaf to incorporate bilingual–bicultural (Bi-Bi) language approach.

Prevalence and Epidemiology

According to the Centers for Disease Control Early Hearing Detection and Intervention (EHDI) Program in 2013, the prevalence of hearing loss in all screened infants was 1.5 per 1,000 (6). Newborn hearing screening is conducted via otoacoustic emissions (OAEs) and Auditory Brainstem Response Test (ABR). The OAE Test operates as an objective measure of hearing by sending sound vibrations through the patient's ear canal and middle ear to the outer hair cells of the cochlea. If the middle ear is clear of fluid and infection and the cochlea working properly, then the outer hair cells will echo the sound back. The ABR is also an objective test that assesses the organs of hearing, auditory nerve, and auditory pathways to the level of the brainstem (7). Some infants who pass newborn hearing screening will later demonstrate permanent hearing loss (8). Although this loss may reflect delayed-onset hearing loss, both ABR and OAE screening technologies will miss some hearing loss (e.g., mild or isolated frequency region losses).

By school age, approximately 6 to 7 per 1,000 can be expected to have a permanent hearing loss (9). Mehra et al. conducted a review of studies looking at prevalence of hearing loss in children and adolescents between 1958 and 1995 and found that the average prevalence of hearing impairment is 3.1% (10). According to the Annual Disability Statistics Compendium, the number of children with disabilities, ages 6 to 21, served in the public schools under the IDEA Part B in Fall 2013 was 5,693,441 (in the 50 states and DC) which reflected 8.4% of the resident population ages 6 to 21. Of these children, 65,502 (1.2%) received services for hearing impairment (11).

Morzaria et al. conducted a systematic review of etiology of bilateral sensorineural hearing loss in children in 2004 by reviewing 780 articles between 1966 and 2002 (12). They found that the most common etiology of bilateral

sensorineural hearing loss is unknown, likely multifactorial. Of the known etiologies, nearly 30% were noted to be due to genetic etiologies including syndromic conditions such as Waardenburg syndrome, Velocardiofacial syndrome, Down syndrome, Goldenhar syndrome, Branchio-Oto-Renal syndrome and the remainder due to nonsyndromic genetic causes. There are many distinct genetic forms of hearing loss interfering with normal conversation. Mutations in the GJB2 gene are the most common cause of inherited congenital deafness (13). Of the prenatal etiologies, it was noted that the majority were due to infectious etiologies such as Rubella, CMV, and measles. Prematurity, kernicterus, and asphyxia accounted for the majority of perinatal etiologies. In childhood, recurrent otitis media with effusion accounts for the bulk of hearing loss which, if caught early and treated with myringotomy tubes, permanent damage can be minimized.

Developmental Considerations

Historically, the concern with hearing loss has been the deprivation of language, owing predominantly to the inability to acquire oral spoken language (14), particularly since more than 90% of deaf children are born to hearing parents (15). Deafness and its consequences on developing oral language can have a profound effect on other domains of development given its influence on cognition and social behaviors. During the developing preschool years, when hearing children gain sufficient mastery of spoken language to express needs, desires, and emotions, the deaf children of hearing families are confronted with tremendous obstacles.

This concern about oral language acquisition has been one of the reasons that roughly 40% of children who are born profoundly deaf receive a cochlear implant per the U.S. Food and Drug Administration. According to the Agency's analysis, as of December 2012, in the United States, approximately 96,000 cochlear implants were implanted in patients. This number constituted approximately 30% of all devices implanted in patients around the world. Also, in the United States, approximately 60% of the cochlear implants (N = 58,000) were implanted in patients who are 18 years of age and older, while the remaining 40% of the cochlear implants (N = 38,000) were implanted in pediatric patients who are 17 years of age and younger. Furthermore, approximately 26% of the cochlear implants (N = 25,000) were implanted in children aged 5 and younger (16).

Language Development

Language is the tool for formulating thoughts and is differentiated from speech (articulation) or communication (which is an interactive and reciprocal exchange). A deaf baby babbles at the same age as a hearing baby. The deaf baby ceases to babble when babbling becomes social and infants begin to model the sounds they produce on

the sounds they hear. There are wide variations in the milestones of the onset of speech in hearing children. The deaf child's lack of response to sounds might be rationalized away. For the hearing parents, the delayed and startling diagnosis of deafness requires a dramatic reorientation of their conceptualization of their child. The parents are faced simultaneously with a major decision as to the type of language acquisition training including manual or sign language, oral language, or total communication which encompasses both, often in the face of conflicting professional opinions. The campaign against the use of manual language was based largely on the misconceptions that oral language is necessary for abstract thought and interacting with the hearing world, and that sign language is not a true language. Noam Chomsky's suggestion of an innate preprogramming for the process of language has been widely supported (17). Spontaneous sign systems observed in children of different cultures contribute to the understanding of the innateness of language in human infants (18). Observations that the syntactic structures and processes of language development of deaf and hearing children are similar lend support to the expanding use of sign. Stokoe et al. demonstrated sign language to be a true language through linguistic analysis of ASL and publication of the first dictionary of ASL that was based on linguistic principles in 1965 (19).

The hearing child with hearing parents learns spoken language through environmental interaction. The deaf child learns communicative language by visual means. The position of oral language proponents is that the deaf child will be unable to interact with the dominant hearing population without some spoken communication. Support for early auditory amplification and training is encouraged, so that the process of vocalization and babbling can be preserved and the concept of sound for communication and shaping of the vocalizations can be facilitated. The manual argument asserts that the vast majority of deaf people ultimately enter deaf culture for social and personal needs; therefore, they should feel comfortable with and accomplished in the language of their culture. The potential psychological conflicts in this dichotomy, which confront the consulting psychiatrist, are highly emotionally charged. This controversy is not dissimilar to the debates on bilingual education and accommodations to diversity and multiculturalism. Oral training is demanding; its proponents state that signing hinders its successful mastery. There remains great heterogeneity of achievement within both the oral and total communication groups and varying degrees of success in formal language acquisition. The tragedy of this politically charged controversy is that parents are required to make a lifelong decision for their child while facing emotional upheaval. Child psychiatrists' greatest value during the child's crucial cognitive and social development period may be to help parents teach acceptable behavior, including rules, compromise, and delayed gratification. This may be particularly difficult when the parent is dependent on only a “yes” or “no” response in exclusive oral communication.

The eventual language preference among deaf young adults balances the nature of the residual hearing, quality of early training, usefulness of communication, and cultural orientation of the individual toward the hearing world or deaf culture social groups. Many adults develop bilingualism in varying degrees but the issue of language and social isolation persists with varying psychological consequences. The deaf child in a hearing family tends to be isolated irrespective of communication. Deaf adolescents trying to function within the hearing environment particularly complain about their difficulty at parties and dances, where lowering of lights and background dance music makes communication and flirting almost impossible. To conceptualize such difficulties, consider the child who encounters any number of situations where vision and hearing are used and coordinated simultaneously, such as class note taking, talking at the dinner table, or honking cars warning of danger. Many children who later prefer to use sign but whose parents do not, often view the parents' lack of communication skills as evidence that they do not accept them. Sibling interactions with the deaf child also affect self-perceptions and social skills. Adolescents often try to fake hearing and discard aids with frequent negative consequence in self-concept.

Cognitive Processes and Theories

Cognition is linked to language acquisition. Areas of exploration, including memory, visual-motor and perceptual-motor functions and problem-solving strategies are being pursued with advanced technologies, an increased knowledge in the basic neuroscience, neuropsychology, and rehabilitation therapies. Reported intelligence quotient (IQ) scores and academic achievement are concerns for the child psychiatrist but scores can be misleading. The most commonly used tests among deaf children are the performance subscale of the Wechsler Intelligence Scale for Children, 4th edition (WISC-IV) and more recently the Wechsler Intelligence Scale for Children, 5th ed (WISC-V, 2014). The Leiter International Performance Scale, Wechsler Preschool and Primary Scale of Intelligence, 4th ed (WPPSI-IV, 2012), Goodenough Draw-a-Person Test, Kaufman Test of Educational Assessment, 2nd ed (KTEA-II), the nonverbal section of the Kaufman Assessment Battery for Children (K-ABC), Test of Nonverbal Intelligence (TONI) and Test of Early Reading Ability-Deaf or Hard of Hearing (TERA-D/HH) are also used for cognitive assessments in Deaf/Hard of Hearing children. The Wechsler scales were not designed for hearing, visual, or motor impairments. As stated in the WISC Manual, although one may prefer to place greater weight on the performance subtests to estimate the cognitive ability of a child with hearing loss, the WISC was not standardized with modifications. If sign language and other visual aids are necessary to give instructions to a deaf child, the evaluator and presumably the clinicians who are likely to use the tests scores should recall such alterations to have an impact on

scores. For infants and preschoolers, developmental measures such as the Bayley Scales of Infant Development, 3rd Ed (BSID-III), Gesell Developmental Schedules, or Cattell Infant Intelligence Scales are used.

The following are considerations in the psychometric testing of deaf and hard of hearing children: The instrument should be nonverbal, because a verbal instrument can reflect language rather than cognition; there is greater likelihood that the instrument will report a falsely low score than a falsely elevated score; there is increased potential error when the test is administered by an examiner not familiar with hearing loss, unable to communicate instructions in the child's preferred mode; personality tests are difficult to interpret because subtlety of instructions might not have been communicated and responses may be limited or unintelligible; and testing of preschool children at whose age communication skills are only beginning to develop is vulnerable to error and underestimation of potential. Krouse and Braden investigated the validity of the WISC-IV and found that the scores are at least reliable in terms of internal consistency for deaf/hard of hearing students as they are for normal hearing students (20). Verbal tests of intelligence are not recommended for the cognitive assessment of deaf and hard of hearing individuals (21). Braden found little correlation of the nonverbal, WISC-R Performance Scale k(PS) IQ to academic achievement using the Stanford Achievement Test-Hearing Impaired Edition (22). This suggests that the criterion of academic achievement fails to be an accurate reflection of the deaf child's innate cognitive abilities. Currently, many schools for the deaf use total communication where the teacher articulates and uses sign. The educational outcome of impaired children who have been mainstreamed is still uncertain, as is the long-range achievement results for deaf children taught by total communication. However, it is most likely that the psychiatrist will evaluate a child with academic delays or unevenness in achievement.

Social Development

Language status influences social development and subsequent behavioral difficulties. The impact of deafness on child development can be readily observed in infants' orienting behaviors. Hearing children can hear their mother coo to them and orient toward their direction. They learn that crying attracts their mother's attention even out of sight. This experience is not available to the deaf child. Teaching social rules and concepts or right and wrong cannot be done easily by explanations, and the child often perceives limit setting as capricious. The child's developing theory of mind, as an interconnected network of beliefs, desires, and feelings influencing behavior, can be helpful in understanding social, emotional and cognitive development. Peterson and Siegal have developed a theory of mind from studies of prelingual signing deaf children (23). The influence of deafness on development can be understood in light of various theories of development, for example, Eriksonian

developmental stages, Bowlby's attachment theories, and so on. Vaccari and Marschark have explored the role of effective parent–child communication in the social and emotional development of deaf children (24).

The prevalence of reported emotional and behavioral problems among deaf children is three times that of the general pediatric population. In summarizing various reports, Meadow and Trybus find deaf children to be described as hyperactive, immature, and impulsive (25). There is a general impression that a typical "deaf personality" exists. Personality features usually included are characteristics such as impulsivity, hyperactivity, rigidity, suspiciousness, and immaturity. Following other investigators who have challenged these suppositions, Chess et al. used a sample of 248 children with congenital rubella followed longitudinally from age 2.5 to 14 years. They concluded that deafness does not confer a "typical personality"; it is the behavioral symptomatology of those with neurologic damage that is largely responsible for such a stereotype in the rubella-deaf (26). Application of stress and coping models in studying adjustment indicate that social support is predictive of maternal adjustment and that maternal problem-solving skills are significant predictors of child adjustment (27).

Adolescent development poses different difficulties because information comes primarily from peers and the environment outside of the home, at the mall, pizza parlor, or street. By this age, deaf teens who are ASL users have a social network within the deaf community, obtaining information not accessed from hearing parents or other adults. Landsberger et al. conducted a study to look at psychiatric diagnoses and psychosocial needs of outpatient deaf children and adolescents compared to hearing counterparts. Over one-third of deaf youth had impaired family relationships, living situation, communication, judgment, and physical health (28). Charlson et al. have reported as an in-depth evaluation of successful deaf teenagers (29). All of their subjects reported some degree of isolation from hearing peers or family that was associated with communication difficulties. Their sample included deaf teenagers with deaf and hearing parents, and residential schools. Most of the students had developed a strategy for coping with the isolation, further raising the impact of parent's signing skill on adolescent social development, highlighting deafness as a significant variable in the task of developing sense of autonomy and competence.

Psychiatric Evaluation of a Deaf or Hard of Hearing Child or Adolescent

The evaluation, treatment, and management of deaf children with psychiatric disorder is intimately related to the child's communication (30). Beyond the general techniques of child psychiatry interviewing, the examiner should focus on the preferred mode of communication for the child and be prepared to function within that modality. Assessments should include the parent's ability to communicate in the

child’s preferred mode, the impact of the parent–child communication and alternative, nonverbal interactive strategies of parents and their deaf children (31). For preverbal and nonverbal children, a behavioral analysis with detailed information from long-term caregivers helps to interpret the child’s behavior. The oral child relies on lip-reading cues; hence, the examiner should provide a continuous unobstructed view. To communicate with a deaf child, a gentle touch or waving the hand in the child’s visual field is acceptable. The examiner should not sit with the sun or a bright light behind the back, creating shadows and eyestrain. If the child’s preferred mode of communication is sign, a certified sign interpreter is required for an examiner with sign skills adaptable to the level of the child or adolescent. A family member is unacceptable, because the child is not free to communicate confidentially. The interpreter is best situated next to the examiner, allowing the child an unobstructed view of both examiner and interpreter.

The syntax and grammar of ASL, as with other languages, are completely different from those of English. ASL is a distinct language, not a codified form of English. When ASL is translated word for word, the language form appears fragmented and disorganized, and has been confused with psychotic processes (32). Formal language defects are often similar in sign language to those found among hearing populations, with changes in rate of production, echolalia, perseveration, and neologisms. The assessment of language and communication is fundamental to any psychiatric evaluation and particularly vulnerable to errors in assessing a child with hearing loss. Even good speech readers understand a limited percentage of the mouth and lip formations without cues. Effective communication requires constant concentration, guesses, adequate vocabulary level, quality training, and experience. The common use of idioms and slang in verbal conversations can present problems when working with oral (speech–reading dependent) youngsters. For example, an oral deaf adolescent boy considered to have excellent speech–reading skills responded with an inappropriate response to the quotation, “when push comes to shove.” After a prolonged effort to understand and explore the bizarre response, it appeared that the youngster had speech read, “put it on the shelf” and that his response was congruent to that reading.

Proverbs that are used in psychiatric examination for the hearing are misleading. Many proverbs have no meaning to the deaf, such as, “The squeaky wheel gets all the grease.” Many words and phrases routinely used in mental health settings adapted from physical medicine assume a mental health, context-dependent meaning. For example, “How are you feeling?” has elicited the response, “Nothing” from a crying deaf adolescent because she had no physical pain. A common vocabulary is important with children and adolescents; and a determination whether they know the sign “emotion” and its connotations is critical. The examiner might list for the child the signs of happy, sad, and the like, interspersed with some simple nouns to find if the patient can distinguish which are emotions. Deaf individuals have hallucinations,

look into space, and even sign into space toward the source, but it is not helpful to pursue the question, "Are you hearing voices?" Some may report that people or sources such as loudspeakers are talking about them or commenting specifically to or about them. This must be distinguished from prevalent beliefs often true within deaf culture that hearing people talk about them behind their backs. Schneiderian first-rank symptoms can be elicited, but ideas of reference must be teased away from cultural belief systems and experience. The psychopathology of paranoia poses similar problems. Drawings can be helpful in finding psychodynamic material. The Goodenough Draw-a-Person Test can provide an estimated intelligence level. House-Tree-Person Test and Family Kinetic Drawings are helpful in gathering projective material and exploring relationships. It is best to interpret the drawings based on a story obtained about the drawing. Questions about what is happening, what the subject of the drawing is thinking, feeling, and hopes for the future prove richer than the usual theoretical interpretive formulations of symbolic meanings. Psychometrically sound functional scales specific to this population may further clarify symptoms and adaptive functioning.

Differential Diagnosis

Intellectual disabilities need to be ruled out in a deaf child or an adolescent with problem behavior. Autism spectrum disorders, childhood schizophrenia, ADHD, depression, conduct disorder, and parent–child conflict need careful consideration. ADHD occurs in 3% to 5% of the general childhood population and in 6.6% of children with hearing loss (33,34). Delays in academics or simple knowledge about the world may present as immaturity, dependency, or educational delay. Deaf children are accustomed to routine sequences of actions because their parents and mentors find it difficult to explain changes. They themselves may later insist on sameness, leading to a misdiagnosis of childhood schizophrenia, autism, or obsessive-compulsive personality disorder. In a deaf child, alternative causes must be considered for all these diagnoses.

Differential diagnosis of behavioral disturbances among deaf children requires the clinician to consider unusual presentations of conditions that exist in hearing children. Tinnitus that occurs among deaf children may be mistakenly diagnosed as hallucinations. The assessment of multiply disabled deaf children requires a large team of highly specialized evaluators including audiologists, speech–language pathologists, teachers of deaf/hard of hearing and certified sign language interpreters (certified ASL interpreter and certified deaf interpreter [CDI]). The position paper on recommended assessment procedures for these youngsters adopted by the Conference of Educational Administrators Serving the Deaf provides a useful and comprehensive listing of all the areas that need to be considered (35). IDEA and PL99-457 that establishes early intervention strategies for children 0 to 3 with

developmental delays and handicapping conditions identify areas that need consideration. In evaluating a deaf child with comorbid diagnoses, the psychiatrist is cautioned from automatically placing the sensory-related issue as the primary issue. This could inadvertently underestimate other impairing conditions such as intellectual disability, ADHD, psychosis, central nervous system syndromes, and so on, which might more accurately dictate functional capacity, treatment, and prognosis.

Treatment and Management

Deaf and hard of hearing professionals have a vital role in providing mental health services to deaf children and adolescents. Intervention strategies utilizing evidenced-based approaches always should be considered. Offering services to support parents, enhance their coping skills, and develop their own support system is an integral part of providing services to this population. A developmental approach in providing services requires recognizing the parents' and children's varying needs at different ages and family stages. Management of the different developmental trajectories and unevenness in various developmental domains needs a wider array of viable modalities of communication, such as sign, play, art, movement, and so on. Prioritizing treatment and subsequent management is like that for other children presenting with psychiatric disorders.

Effective communication is a high priority for primary prevention and treatment of emotional–behavioral disorders in deaf and hard of hearing children. Child and adolescent psychiatrists who work in the field of deafness place a high priority on social/emotional development, psychosocial group identification and support, and a sense of self-identity, which is the core of deaf culture based on sign language. The well-versed practitioner is one who is able to help the family and patient weigh the benefits versus risks of which communication option to pursue, be it sign language or oral language or total communication. The selection of total communication or oral training depends on a number of factors, but it is best addressed by helping parents weigh the pros and cons of each. Parents are often not fully aware of the options as they are interfacing with the medical community and may have limited access or awareness of the Deaf community. To lead parents one way or the other may not ultimately be in the best interest of the child or the family (36).

Treatment focuses on the acquisition of acceptable behaviors for the developmental period, if the behavior problem is not owing to independent psychiatric conditions. Behavior modification has been successful with deaf children, as group psychotherapy has been with deaf adolescents. Group psychotherapy provides an avenue to share feelings and behavioral strategies, particularly around maturational and adjustment issues. Studies proving efficacy of individual psychotherapy in the language used by the child are limited only by the availability of therapists. Clinical reports on the value of psychotherapy tend to be

single-case studies or highly selected samples. Hearing therapists are most successful if they use a transcultural model and acquaint themselves with the cultural beliefs of their clients. As in psychotherapy of the hearing patients, the therapist is advised to convey, “Teach me what your experience is like” rather than, “I know how you feel.”

Evaluating psychopharmacologic agents and monitoring their desired and adverse effects is similar to hearing children with the same symptomatology or disorder, but with a warning. Psychoactive medications, especially neuroleptics, can be used successfully with deaf children for management, but the common anticholinergic side effects of psychoactive medications must be made clear, although they are difficult to communicate in sign language. The blurry vision often experienced with these drugs is intolerable for an individual dependent on vision and limits the usefulness of such medications.

Stimulant medications can be used effectively for ADHD in carefully diagnosed cases. Hyperactivity in hearing-impaired children may be confused with a reaction to poor communication or learning social cues and appropriately responding to them. The determination is complicated by reported impulsivity among deaf children. Cases referred for stimulant medications have identified overwhelmed parents lacking communication skills, having trouble setting limits, and overusing physical punishment to establish their authority. Kelly et al. evaluated a state residential school for the deaf and obtained ratings on 238 students using the Conners Parent Rating Scale and the Attention Deficit Disorder with Hyperactivity (ADD-H) Comprehensive Teacher Rating Scale (37). They found that the Conners ratings statistically differed from normative numbers for hearing children. Among those youngsters who were considered positive for ADD-H, hearing loss tended to be acquired (e.g., bacterial meningitis or congenital rubella). A wide range of management interventions, including stimulant medications, also was reported (38). The decision to use stimulant medication should consider that the chronic nature of the deafness often results in lifetime use of medications to maintain the child in the least restrictive environment. This dilemma can be addressed only on a cautious, case-by-case basis with careful monitoring and periodic assessments. Repeated failures at nonpsychopharmacologic intervention warrant a trial of medication including treatment goals and a time frame for the medication trial as well as a periodic review of the medications with a risk benefit analysis of optimum medication dosages.

Treatment and management includes counseling and supportive measures for the family. Emotional reactions of parents to a deaf child can interfere and/or limit their capacity to respond to their child’s needs. A deaf child’s temperament and the concept of goodness of fit should be considered (39). Siblings are a sadly neglected group requiring intervention and education. Family therapy with a hearing family and deaf child should use interpreters, even if the therapist can sign (40,41). Counseling

for both the parents and siblings include teaching technical information in terms that can be understood clearly.

The first experimental cochlear implants on adults were performed in the early 1960s and clinical trials began in 1973. In 1984, the Food and Drug Administration (FDA) approved the devices in adults. The first implant trial on children was initiated in 1980 at the House Ear Institute in Los Angeles, California (42). By 1990, over 500 children, ranging in age from 2 to 17 years, had received the device when the FDA gave approval for implantation in children. Initially, the Subcommittee on Cochlear Implants of the American Academy of Otolaryngology stated that pediatric candidate selection required failure of benefit from appropriately fitted hearing aids and other devices, the absence of severe organic brain damage, psychosis, severe intellectual disability, personality traits that may interfere with training, and/or unrealistic expectations (43). Criteria and indication for cochlear implantation have changed over the years. For the most optimal benefit for oral language, there is still the recommendation for early implantation in prelingually deaf children and even additional disabilities are no longer considered contraindications (44). Cochlear implantation requires active long-term participation for parents and children. The decision to use this prosthesis is neither easy nor obvious (45). The concept that deafness is not a disability requiring intervention is a position held in deaf culture (46). Fink et al. developed the first longitudinal multicenter, national cohort study to evaluate systematically early cochlear implant (CI) outcomes in children called The Childhood Development after Cochlear Implantation (CDaCI) study. One of the key objectives of the CDaCI study was to better understand cognitive, social and emotional development as it relates to language acquisition. It was noted in the study that early cochlear implantation increased oral language communication skills and improved overall parent-child interactions. With improved oral communication skills, there is implications for overall positive outcome in social/emotional functioning (47).

BLINDNESS AND VISUAL IMPAIRMENT

Definition and Historical Note

Blindness was legally defined by the American Medical Association in 1934 as “central vision of 20/200 or less in the better eye with corrective glasses, and a visual field subtending an angular field of no greater than 20 degrees in the better eye.” This definition, originally for the purpose of determining eligibility for federal insurance programs, has endured and is used in Public Law 94-142, 1975. “Legal blindness” remains a definition used by the US government to determine eligibility for vocational training, rehabilitation, schooling, disability benefits, low vision devices, and tax exemption programs. It is not a functional definition. A child who is

legally blind may have residual useable vision, able to read large-type materials and learn through limited visual input (48). There are alternative definitions of blindness, low vision, and visual impairment that focus on functional capacities, rehabilitative potential, and the nature and quality of the residual vision on educational perspectives; however, there is no consensus about which criteria or classification system to use. Both the National Federation of the Blind and the American Foundation for the Blind indicate there is no generally accepted definition for "visual impairment" as it is a general term describing a wide range of visual function with many different definitions (48,49).

The child and adolescent psychiatrist in practice will likely encounter the World Health Organization's classification system in the International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10-CM) for medical coding and reporting in the United States. The ICD-10-CM defines four levels of visual function: (1) Mild or no visual impairment (2) Moderate visual impairment (3) Severe visual impairment (4) Blindness. These levels are based on presenting distance visual acuity (in feet) and are further refined into nine categories by designation of monocular/binocular, no light perception, and unspecified. The levels of "severe visual impairment" (visual acuity worse than 20/200 but better than 20/400) and "blindness" (visual acuity worse than 20/400) meet the definition of "legal blindness" (50).

Prevalence and Epidemiology

The collection of statistics on prevalence and etiology of visual impairments is challenging due to inconsistent measuring criteria and the varying definitions of vision loss which include blindness, total blindness, legal blindness, visual impairment, low vision, functional limitation in seeing, and severe limitation in seeing (51). The United States does not keep a national register of blind or visually impaired people. Almost all statistics on blindness are estimated, meaning numbers found in a sample are extrapolated to the entire population. However, each year, the American Printing House for the Blind polls each state for the exact number of legally blind children through age 21 enrolled in elementary and high school to determine eligibility to receive free reading matter in Braille, large print, or audio format. The 2014 survey of the American Printing House for the Blind reported 60,393 students who were registered as legally blind. Of that group, 29.2% were classified as visual readers, 8.5% as Braille readers, 8.5% were in residential schools, and 2.3% were in programs for multi-handicapped individuals (52).

The WHO in 2006 has listed childhood blindness as the cause of 3.9% of blindness and visual impairment worldwide with cataract (47.9%) and glaucoma (12.3%) topping the list. "Vision 2020: The Right to Sight" is a global initiative with the mission to eliminate the main causes of all preventable and treatable blindness by

the year 2020. Since its launch in 1999, a high priority has been eliminating the 45% of children with visual impairments and blindness from the avoidable or treatable causes of corneal scarring (mainly from Vitamin A deficiency and measles), cataract, retinopathy of prematurity, refractive error, and low vision (53,54). Two of the historically common causes of early vision impairment and blindness have decreased over time owing to medical advances: ophthalmianeonatorum with the routine placement of silver nitrate solution drops in newborns eyes, and retinopathy of prematurity with careful use of oxygen in management of prematurity and earlier detection and intervention (53,55).

Vision loss in childhood caused by congenital, genetic, or prenatal congenital conditions represents approximately 50% of cases. Lymphocytic choriomeningitis causing chorioretinitis in utero is believed to be responsible for some (56). Other causes include optic atrophy, retinitis pigmentosa, optic nerve hypoplasia, cataracts, foveal hypoplasia, persistent hypoplastic vitreous, and microphthalmos. Uveitis potentially leading to blindness can develop in children with juvenile rheumatoid arthritis (57). Cortical visual impairment caused by a disturbance of the posterior visual pathways in the occipital lobe is most commonly caused by perinatal hypoxia, cerebral vascular accident, meningitis, and acquired hypoxia. Most children with cortical visual impairment have other associated neurologic abnormalities (58).

Developmental Considerations

Visual impairment has a significant and far reaching effect on all areas of development. Delay in all milestones is most evident in the preschool period, although obvious challenges remain in making progress at school. These delays are inevitable when consideration is given to the increased cognitive demand of tasks achieved without the benefit of the information provided by vision (e.g., the concept of object permanence and joint attention) (59). Children with vision limited to only awareness of light or light-reflecting objects show the greatest delay (60), between 1 and 2 years' delay compared to sighted peers.

Visually impaired children suffer the full range of clinical psychiatric syndromes. However, commonly observed behaviors in blind children, such as stereotypic rocking, passivity, and immobility, do not signify psychiatric illness, nor is late achievement of motor milestones reflective of cognitive problems. Such behaviors may be due to the visually impaired child's reliance on caregivers for environmental stimuli as well as insufficient environmental response. Developmental delays and maladaptive behavior among visually impaired children result from failure to learn adaptive skills or to correct maladaptive behaviors stemming from gaps in the teaching of social norms and behaviors given the paucity of incidental learning.

An additional consideration is the effect of the diagnosis of the child's visual impairment on the sighted parents who often react initially with shock and disbelief

(61,62). Some parents experience considerable distress. It has been observed that parental depression and insufficient understanding of their baby's apparent lack of response can lead to decreased interaction between child and parent at a time when the infant is dependent on the parent for increased input and responsiveness from the environment to offset the lack of visual stimulation and feedback (63–65). Eventual positive parental adaptation to these reactions is usual, but may need appropriate support (66).

The quality of language used by parents is also affected by the presence of visual impairment. Parents have been found to be more directive and less contingent on their children's communicative cues (64) further decreasing the perception of control in the environment on the part of infant. Lowenfeld has observed the subtle but profound influence on the child's development that perception of control of their environment, and self in relation to it, can have (67). In the sighted child, seeing overcomes distances and provides a quick way to evaluate new or changing situations or emergencies. Vision provides the means for observing the behavior of others, especially parents or peers, and learning by imitation while obtaining immediate feedback through observing facial expressions or other nonverbal cues. Early face recognition and social smile by the infant along with eye-to-eye contact are important both to the infant and caretakers in establishing and developing affective bonds. Longitudinal studies of early development in children with visual impairment suggest that attachment formation may be significantly affected (64).

Moore and McConachie (68) found that mothers of blind children, when playing with their child, talked less about objects that their child was actually attending to at the time. The findings suggested that it is very difficult for parents to "think themselves into" what their child finds salient (69) and to ascertain what a blind child is actually focusing attention on and hence what to talk about. Blind parents of blind babies appear to have fewer obstacles to natural effective communication and have greater reliance on close proximity and touch (70). Given the child's dependence on gaining information through language, maintaining a "stream" of language (71), which is responsive to the child's activities and interests (72,73), appears important.

Vision provides the infant and young child with stimulation and observation to permit imitation and modeling, and to encourage and motivate exploration necessary for further development. This includes all domains of motor, language, cognitive, and social skills (74). The blind child is at a particular disadvantage with imitative learning. The constraints of lack of vision on learning are complex and the impact of delay in one area of development is likely to have secondary effects on other areas of development, so that the effects are cumulative (75).

Language Development

Language development for the blind and the sighted infant are essentially equivalent through the babbling stages but can be stunted without visual stimuli (76,77). Language development relies on an understanding of joint reference and developing the concept of symbolic understanding. The early opportunities that sighted children have to see objects and to establish joint reference to objects named by parents repeatedly in the first year of life before language develops is lost to the blind infant. Limited experience in general, and not only visual, may play a role in delaying language acquisition, as may parenting style including being more directive and less contingent on the child's communicative cues or withdrawing and having less interaction.

The visually impaired child must rely on verbal descriptions provided by the sighted to describe words that have a visual meaning. A blind hearing child can locate a bird by its sound but not describe its shape, size, or flight. Although the tactile sense can describe concrete objects that can be held in the hand, it does not help to describe clouds, stars, or colors, nor can the child experience a very large or small object. Without the experience of knowing through sight, verbalized descriptions repeated by the blind child can seem shallow or meaningless and are referred to as "verbalisms," the use of words whose concrete referent is unknown to the speaker. Rosel et al. have shown that all children regardless of their visual status, tend to use verbalisms in much the same way with frequency of use increasing with age but not affected by degree of sight or gender. This is interpreted as pointing to the positive capacity of children who are blind to adapt to the general linguistic behavior of the community in which they live. It also points to accepting that verbalisms in the language of children with visual impairments are normal rather than representing a cognitive or personality flaw or being a psychopathologic indicator as historically postulated by Cutsforth in 1951 (78,79).

Differences in the style of language development have also been described, for example, the use of multiword phrases, linked to familiar social routines, before the use of noun labels. This has been referred to as a more expressive rather than referential style of language use (80). Children with visual impairment also have a tendency to continue with immediate echolalia longer than sighted peers (81). Delays are also seen in the appropriate use of personal and other pronouns and the use of spatial–relational words (e.g., here-there) (82).

Motor and Perceptual Development

The early motor developmental milestones of the blind infant are similar to those of the sighted child until the age of 4 months (83). After this period, the lack of visual stimulation as motivator for the child to explore and interact with the environment can lead to delays in crawling, walking, reaching, grasping, and bilateral hand coordination. The blind child tends to lag behind the sighted in motor tasks where

visual stimulation is a motivator, whereas there is little difference when the task is purely neuromuscular (e.g., sitting or standing alone) (84).

The environment may interact in limiting acquisition of skills when parents are more protective and cautious about giving their blind child the opportunities to explore. Temperamental factors in young children will also play a role; for example, a timid child, having learned to walk, may be more reluctant to “launch” herself into the world than a more adventurous one.

Developing reach and interest in play depend on developing concepts of sound localization and object permanence. Babies without vision require the support of their parents and caregivers to learn these concepts (85,86). Prolonged period of immobility and limited environmental stimulation for the blind infant can result in poor development, especially in the areas of initiative and self-confidence.

Cognitive Development

Cognitive development has been shown to be influenced by many variables including the severity of visual deficit, residual vision, timing of onset (congenital, early or late), personal experience, “innate IQ” and other factors such as motivation that are difficult to define and measure (64,87).

Cattaneo and Vecchi (87) review the neuroscience evidence that mental images or mental representations are important in the development of memory, reasoning, and creative problem solving, and that vision is not necessary for the development of this mental imagery so important in learning, navigation, and many other aspects of daily life. Evidence points to persons born without vision generating mental images similar to those of persons with sight, containing both accurate spatial relations and nonvisual sensory details (87). Cattaneo and Vecchi theorize that vision is not necessary for imagery formation as imagery is primarily spatial rather than visual. Multiple senses or modalities contribute to the generation of mental images. In sighted persons, vision is generally the dominant perceptual experience and is important in the development of multisensory integration or the interaction between the senses (87,88). In individuals without significant input from vision, the other senses play a greater role in perceptual input for mental images, but the multisensory integration is affected given the more sequential nature of the nonvisual sensory inputs (e.g., tactually examining a large object requires doing so one section at a time). Vision allows for easier simultaneous processing of sensory inputs (87,88).

Simultaneous rather than sequential cognitive processes may be a factor in modulating cognitive development. Cattaneo and Vecchi describe the case for sensory compensation or enhanced sensory acuity in the functioning senses through brain plasticity, which allows the functioning senses to recruit the portions of the visual cortex not receiving visual input (87). Occipital activation in blind subjects during Braille reading potentially reflects both sensory and higher-order (language-

related) cognitive factors as some studies have suggested that early visual cortex recruitment during Braille reading tasks might actually reflect linguistic processing (87,89,90).

Learning to read through the use of Braille is potentially a more complex process than learning to read using vision, because it entails linguistic, motor, and spatial skills (64,91). Children with visual impairment may therefore make slower progress in the early stages of acquiring literacy, and this may also delay the recognition of other specific learning difficulties. The long-term follow-up study of children with visual impairment by Freeman et al. (92) found better than expected academic outcomes, with 76% having completed secondary education and 19% having attended or attending university.

Social and Emotional Development

Children with visual impairment face considerable challenges in social and emotional development (63,93,94). Attainment of social skills, such as learning to read nonverbal communication cues, initiating and maintaining interactions, and using eye gaze to regulate interactions (95) are highly visually dependent. Nonverbal social cues and body language are not available to the visually impaired child, complicating the development of peer and social relationships, as they are not able to see and learn the skills through observation (96,97). Despite this limited feedback from their environment, Mulford (98) found that most blind children (aged 5 to 6 years) had established a range of verbal and nonverbal communication strategies for establishing referential communication. However, Preisler (99) found that blind children rarely initiated and had difficulty maintaining social interactions and related much more to adults. Interactions with peers were more extended in structured play but they had more difficulty in free play settings. Children with visual impairment do not display a full range of play behaviors and demonstrate compromised social interactions, engaging more in solitary nonsocial play (96). The child's inability to imitate may inspire reluctance on the part of caretakers to introduce a wide variety of toys to the child, hence, social skills are hampered owing to the visually impaired child's paucity of interactive play experience. Adults' interventions to promote social contacts may focus the child's attention toward the adult and not the playmate.

The socially isolated child who is only around adults has no way to learn age-appropriate social behaviors. Despite this, many visually impaired children and adolescents are skillful at interpersonal manipulation. A long-term follow-up of children with visual impairment into adult life (92) found that half had a romantic relationship and 20% were in partnerships, all with sighted people.

Lowenfeld (67) describes four major concerns that present difficulty to the visually impaired adolescent: sexual curiosity, dating, mobility, and concern for the future. The inability to gather sexual information from observation or magazines

might compel the sexually curious adolescent to behave in a manner that would violate cultural and social taboos. Dating is an important arena in which one develops self-confidence and asserts a gender role, but ability to date is dependent on meeting another person and engaging in rituals of flirtation and personal appearance. The visually impaired must rely on introductions and arrangements that diminish flexibility and self-confidence while invading privacy. Limited mobility reduces opportunities for the separation and individuation process to occur, which further limits autonomy. Concerns for the future that involve leaving a protective family or school setting, accepting vocational challenges, ensuring economic stability, worrying about marriage, and the genetic transmission of the visual impairments pose significant hurdles.

Psychiatric Evaluation of the Blind or Visually Impaired Child or Adolescent

As a general principal, the child and adolescent psychiatrist is cautioned against using a "deficit model," assuming that damage is inevitable with a perceptual impairment, or at best only partially compensated, and always results in personality and/or psychiatric disorder. The examiner should be aware of myths about the blind such as innate helplessness and total dependence, blindness as a punishment for sins, etiologic association with venereal disease, and belief of hyper acuity of other senses. Prior to the interview, the examiner should have knowledge of the child's medical history, degree of independence and cognitive level, events in the home, school adjustment, purpose of the referral, and the child's ability to modify behavior. The age of onset of blindness and presence of residual vision are major considerations.

The child psychiatrist evaluating a visually impaired child must be prepared to touch the child more than he or she would touch sighted children, asking for the child's permission when appropriate. Talking softly to orient the child toward the examiner before even touching or approaching the child helps sets the tone for the evaluation. The child should be led to the examining room, and the examiner may initially remain in continuous physical contact by holding his or her hand or touching the shoulder. The interview space, its layout—including where the child sits and all of the toys available to the child—should be described, so that valid conclusions can be drawn about activity selection. The child will often ask seemingly impertinent personal questions of the examiner, including appearance and marital status, some of which a sighted child or adolescent determines by observation. Whether answered or not, a friendly tone is essential. It is important to note that with sensory impaired children, and more so with the blind and multiply handicapped, any interaction presents an opportunity to teach and engage the child.

The vast majority of legally blind children are better described as low vision, thus

lighting in the examining room is important. There are no fixed rules, but the examiner must be alert to the unique nature of the child's vision and maximize the residual capacities. Glare, background light and shadows, along with placement of objects in the visual field are considerations. A gooseneck lamp on the table enables the child to maximize vision while playing or drawing. Creating nonglare contrast can be helpful to increase visual perceptions. If drawing tasks are to be part of the evaluation, then the table surface should be free of glare. A dull light blue–gray table surface works well, contrasting both white and dark drawing paper or covering a white table with brown wrapping paper is a satisfactory solution. If white paper is used for drawings, then the standard pencil often does not provide sufficient contrast and a black felt-tipped pen or marker would provide better contrast. Some children prefer and respond better to dark drawing paper and a light-colored or white marker.

Play therapy can be used in the evaluation of blind children, but often the child must be taught how to play. The process of learning play through imitation often is not available to the blind child. The clinician can make some valuable observations about the child in the process of teaching a particular type of play. Blind children respond best to very realistic objects or toys. Play is better with utensils that the child routinely uses, such as real fork and spoons, rather than small toys, which have no meaning to the child. Similarly, dolls close to life size with molded realistic facial features and hair elicit more meaningful response as the child fingers the face than would the soft, more stylized, cloth dolls. Dollhouses with realistic figures of people and furniture can elicit helpful information about the home life of the child. The clinician might first have to teach the child how these small objects symbolize real people or furniture. In general, the child plays with toys that are for a younger age group. It is best to start with real props to develop "pretend" imaginative play as part of therapy. The children pretend play verbally by telling stories as opposed to acting out behaviors. The clinician can elicit psychodynamic material and dreams in a verbal form, but the content may seem to be lacking in affect. This lack of apparent substance or affective content or "verbalism" seems more related to the language acquisition process than to the potential for affective content and the alert clinician can piece together the affective web that binds the meaning for the child. The child's total body and other nonverbal responses including gestures as a communicative device need to be considered with the caveat that the child's facial expression may reveal less than he or she understands.

The visually impaired child may be slower to warm up than a typical sighted child. Long silences should be avoided and the child should be notified of the examiner's movements. Anticipated shifts of topic in the course of the evaluation should be announced so as not to confuse or contribute to disorientation. Echolalic language is relatively common and rarely pathologic. Self-stimulating behavior and stereotypic movements are frequently seen and not diagnostic of specific psychiatric conditions. The examiner should speak directly to the child and accept as an

indication of relatedness that the child faces him or her with the ear and not the eyes. In an interesting protocol, Raver-Lampman (100) asked 50 subjects who were informed about blindness and in contact with the blind, to evaluate videotapes of two children without gaze direction and two with gaze direction as they answered questions from examiners sitting on either side of them. The tapes were presented in a random order and opposite recording positions. The results revealed that, when a visually impaired child used gaze direction toward the questioner, the responding subjects rated the child as being more intelligent and socially competent than when the child did not use gaze direction. This serves as a caution to the examiner to be alert to his or her personal bias and unconscious judgments, especially involving the child's body posture and direction of gaze during the evaluation.

It is helpful to indicate that several meetings with the child are normally required when accepting the referral. The clinician should initially be ready to teach the child tools necessary for a psychodynamic evaluation; for example, pretend play and drawing tasks. In effect, the assessment is a functional protocol looking at the child's strengths, learning, and problem-solving styles, and what if any, interfering psychiatric processes are present.

Differential Diagnosis

Differential diagnoses include intellectual disability; autistic spectrum disorder; ADHD; childhood schizophrenia; and conduct and personality disorders, including immaturity, over dependency, and obsessiveness. Repetitive rocking, swaying, or eyeball pressing and other "blindisms" are also seen in other child psychiatric entities, especially mental retardation and autism. When these behaviors are found among blind children, they should be differentiated from a symptom of other conditions.

Blind youngsters may not acquire factual information or develop learning skills without educational opportunities. Early social interaction may have been muted for blind youngsters, and care should be taken in assessing diminished interpersonal affective responses as indicating clinical psychiatric conditions. Superficial symptoms suggesting autism in a blind child often abate when meaningful personal interaction is offered. For reasons of convenience and safety, many parents and caretakers tend to provide unchanging sequences of activity to their children. An insistence on sameness or a severe negative reaction to a change in patterns and activities may be a nonpathologic adaptation to visual impairment and past learning.

Treatment

Early intervention programs with blind infants and preschoolers teach social skills and promote attainment of developmental milestones while supporting the family

structure, thereby preventing psychiatric or behavioral problems. Providing a means of communication and socialization is the first consideration for preventing most conflicts. The blind child learns to speak in the usual manner, but the meaning of words that the youngster cannot experience (verbalisms) is difficult to convey and may cause frustration. Color and the contours of very large objects or very small ones are most difficult to describe. Checking self-appearance for neatness and simple rules of social behavior, such as chewing with lips closed, cannot be learned by imitation and must be demonstrated. Alternate strategies of adaptation to an invisible, barely discernible or at best blurred world must be taught so as to avoid confrontation, tantrums, and shame. A psychiatrist treating a blind child or adolescent may be involved in consultation and serve as a liaison to provide advice on management to parents, family, and the school.

The examiner's familiarity with specific technologies to help the visually impaired may be useful in guiding the family and school to meet the child or adolescent's developmental needs. Computerized magnification, Braille computer, and other literacy devices have been increasingly available to school-age children. Current advances in Global Positioning System via satellites and its application to cane technology have helped increase safe mobility, autonomy, and self-esteem. These new technologies have alleviated concerns and reassured parents and facilitated skill development. Behavior modification has been useful for both deaf and blind children. Changing specific behavior in order to gain acceptance is successful for motivated children. Sharing experiences, feelings, and problems in group therapy and counseling can be very helpful. Erin et al. (101) have provided a helpful review of literature regarding teaching social skills to the blind and visually impaired. They emphasize the value of social skills for a visually impaired child to be successful in mainstream programs. Studies strongly support success in teaching social skills using different approaches. There is the interesting question of whether the goal of social skills training should be to teach the blind behaviors of the sighted rather than other skills more appropriate to the blind. Individual psychotherapy can be invaluable for a visually impaired child or adolescent. The therapist must constantly be alert to the possibility of confusion in the use of language. Although blind individuals cannot follow a description of color, they do use many vision-related idioms, such as "I see" for "I understand." Transition-age youths with visual impairments experience barriers to a successful transition from secondary school environments to work. Interventions that were found to enhance employability skills and self-constructs were also identified in research as predictors of the successful employment of blind youth (102).

Medications can be employed with the same criteria as for nonhandicapped children and adolescents. Medications with the potential of interfering with residual vision should be avoided especially when some vision remains. Melatonin is helpful with treating circadian sleep–wake–rhythm disorders in children with vision

impairment and has been shown to be safe and effective in long-term use (103,104). Stimulant medications can be used for ADHD, giving both child and caregiver an opportunity for better communication, education, and other interactions. Careful monitoring is necessary for adverse effects of increasing agitation or flattening of mood further decreasing the child's motivation for social interaction. Even more than in the nonperceptually impaired, psychopharmacologic intervention should be used judiciously as an adjunct in addition to other psychosocial interventions.

DEAF-BLINDNESS

All that has been said in the introductory sections under the heading of general considerations and role of the child and adolescent psychiatrist is even more pertinent in the case of deaf-blindness. In addition, attention should be given to the sections earlier in the chapter on children and adolescents with either one or the sensory-related loss. Having said that, it should be noted that the effects of a child with multiple sensory-related losses can have even more of an impact on the individual's development and communication abilities as well as the family dynamics than would be seen with a single condition.

Definition

The IDEA (2004) defines deaf-blindness as a condition with "concomitant hearing and visual impairments, the combination of which causes such severe communication and other developmental and educational needs that they cannot be accommodated in special education programs solely for children with deafness or children with blindness" (105). The definition is educational and does not focus on specific clinical presentations, however it does signify that the dual concomitant sensory impairments warrant additional specialized educational intervention above and beyond each condition alone.

Deaf-blindness does not refer to a total inability to see or hear. In reality, deaf-blindness is a condition in which there are varying degrees of vision loss in combination with hearing loss. The range included in the terminology of "deaf-blindness" is great. Barbara Miles, Ed.D, outlined the definition of deaf-blindness in her paper "Overview on Deaf-Blindness" (106). She notes that the deaf-blind child experiences the world in a much narrower perspective compared to individuals who can hear and see. With a child who is both totally blind and profoundly deaf, as was the case of Helen Keller, the "world extends only as far as the fingertips can reach" (106). These children are essentially alone when there is no physical contact with anyone or anything. Children with some residual hearing or usable vision would likely have an enlarged, yet still overall limited, view of their world.

The term "deaf-blind," although professionally widely used, might not accurately

convey the individual client's circumstances. The imprecision in definition highlights the very nature of the clinical work, when the clinician's cumulative experience and knowledge is called to bear on a unique child or adolescent and his or her specific circumstances and needs. As indicated earlier in the chapter, the words "deaf" and "blind" have strong connotations and the combination can be overwhelming. Familiarity with resources and supports for sensory impaired children and their families is essential.

Prevalence and Epidemiology

The data from the National Child Count of Children and Youth who are Deaf-Blind is the first and longest running registry and knowledge base of children who are deaf-blind in the United States (107). Across the United States for the 2013 national count, there were 552 infants (birth to 2 years old old) and 8,847 children through young adulthood (3 years old to 21 years old) reported as deaf-blind. As such, there was a total of 9,454 infants, children and young adults who were identified as deaf-blind (107). The opportunity for early identification, intervention and the provision of instructional services aimed at the unique needs of young children and students who are deaf-blind is a critical component that cannot be lost.

There are many causes for deaf-blindness. There are genetic syndromes such as Usher syndrome, CHARGE Syndrome, Down Syndrome/Trisomy 21 and Trisomy 13 which have high correlations of deafness and blindness. Usher syndrome is an autosomal recessive disorder characterized by congenital deafness and retinitis pigmentosa (with progressive vision loss). It is the most frequent cause of deaf-blindness in adults and accounts for 3% to 6% of deaf children (108). CHARGE Syndrome is a rare genetic syndrome and is an acronym for a constellation of clinical features: coloboma, heart defects, choanal atresia, retardation (of growth and/or development), genitourinary malformation and ear abnormalities. It is associated with a mutation of the CHD7 gene (109). There are also other congenital anomalies associated with deaf-blindness including fetal alcohol syndrome, microcephaly, hydrocephaly and maternal drug use. Prenatal infectious exposure has been linked to deaf-blindness. Congenital rubella syndrome was the most common cause of congenital deaf-blindness but now is greatly reduced due to the use of immunization programs in past 20 years (110). The major causes of deaf-blindness are noted in Table 2.2.2.2 below (106,111).

Some trends were noted on the 2013 National Child Count of Children and Youth who are Deaf-Blind. The distribution of children/youth across age groups has remained relatively stable over the past 5 years, with a slight shift toward a younger overall population. There has been a slight overall decrease in the percentage of the total Deaf-Blind Child Count represented by infants, birth—2 years of age (6.2% to 5.9%). Early identification and referral to the deaf-blind programs continues to be an

issue with less than 100 infants, birth to 1 year of age being included on the Deaf-Blind Child Count (107).

TABLE 2.2.2.2

MAJOR CAUSES OF DEAF-BLINDNESS

GENETIC SYNDROMES:

- Down Syndrome
- Usher Syndrome
- Trisomy 13
- CHARGE Syndrome

MULTIPLE CONGENITAL ANOMALIES:

- Fetal Alcohol Syndrome
- Hydrocephalus
- Microcephaly
- In Utero Substance Exposure
- Prematurity

CONGENITAL PRENATAL DYSFUNCTION:

- AIDS
- Rubella
- Toxoplasmosis
- Herpes
- Syphilis

POST-NATAL CAUSES:

- Asphyxia
- Traumatic Brain Injury
- Stroke
- Encephalitis
- Meningitis

Adapted from Etiologies and Characteristics of Deaf-Blindness, Heller and Kennedy (1994) and Overview on Deaf-Blindness: DB-LINK Fact Sheet, Miles (2008).

The number of children identified as having received cochlear implants has increased from 167 in 2005 to 914 in 2013, more than a fivefold increase during this time period. This increase spans the age ranges, from infants to young adults. Overall, the number of children/youth with additional disabilities has increased. In 2005, over 20% of the children/youth on the Deaf-Blind Child Count had no additional disabilities. In 2013, just over 10% had no additional disabilities. In 2005, just 13.1% of the children/youth on the count had four or more additional disabilities. In 2013, 43% of the children had four or more additional disabilities (107).

The prevalence of CHARGE syndrome continues to increase significantly. In 2013 there were 864 children and youth identified as having CHARGE Syndrome. The identified prevalence of Usher syndrome reached a peak in 2007 and has decreased over the past 3 years (107). As noted above, the rates of congenital rubella syndrome have been on the decline as rates of maternal infection have decreased due to effective immunization.

Developmental Considerations

Much of what has been addressed in prior sections regarding developmental challenges pertain to children with deaf-blindness, with the understanding that the child with multiple sensory-related issues faces challenges above and beyond having one impairment alone. This is why the emphasis is on early detection and involvement in early intervention programs. As such, the National Center on Deaf-Blindness has been committed to this initiative with the Early identification of infants who are Deaf-Blind for the past 10 years (112). With early identification of children in need, there is ability to intervene in a manner to reduce morbidity. Early identification can allow families and intervention specialists to develop appropriate team support for needs and access therapeutic specialists to address both developmental and educational needs (113). In addition, reporting children who are deaf-blind to the State Deafblind Centers for Education census (National Center on Deaf Blindness, 2014) allows continued national and state support and assistance for children with this low incidence condition as well as provides a mechanism to initiate technical assistance and supports for the families and Early Intervention providers (114). In 1966, Jan van Dijk developed child guided interaction strategies to engage, assess and teach deaf-blind children. The movement based approach was known as Coactive Movement and helped to develop language and acquire concepts for successful interaction with their world (115).

Psychiatric Evaluation of the Deaf-Blind Child or Adolescent

The diagnostic process is a collaborative team effort with psychologists, educators, and habilitation and rehabilitation specialists. Techniques for eliciting information, especially physical contact, lighting, and realistic props for toys, are similar to those described for blind children. Evaluation requires time, patience, and the use of an interpreter who is familiar with and to the child if a system of manual sign language has been developed. Meaningful evaluation requires gaining an understanding about the child's perceptions of the world. A child who is deaf-blind, has not had access to the experiences of the world, and therefore the natural incidental learning, that comes readily to the typical child.

Few centers are equipped to provide the comprehensive assessment that a deaf-blind child requires. The psychiatric evaluation has three potential pitfalls:

1. Failure to recognize visual or auditory loss when evaluating a child who is known to be either deaf or blind, but ascribing the behavioral difficulties to a clinical psychiatric illness, most commonly developmental delays, autism spectrum or intellectual disabilities;
2. Diagnosing a child as deaf-blind when only one sensory loss exists concurrently

with a major clinical psychiatric syndrome;
3. Diagnosing cognitive disability, schizophrenia, autism, or organic brain syndrome in a deaf-blind child, based on an unusual presentation, without being fully aware of the child's potential strengths or problem-solving and adaptive abilities.

Miles and McLetchie (116) point to the importance of each experience in developing "concepts" or ideas that give meaning to our world, and caution evaluators not to assume that a child who is deaf and blind has understanding of even the most foundational concepts. Rather each experience within an evaluation can be viewed not only as eliciting information, but also as an opportunity to provide access to the world and contribute to concept development. Establishing mutual attention that is usually accomplished with pointing, often first needs to be through touch with children who are deaf-blind. Miles describes the technique of putting the examiner's hand alongside and gently under the last two fingers of the child's hand allowing for exploring through touch together without the examiner's hand on top forcing or directing movements (116).

Differential Diagnosis

The common differential psychiatric diagnoses in deaf-blind individuals include intellectual disability, autism spectrum disorder and other neurodevelopmental disorders, childhood schizophrenia, and reactive attachment disorder. One of the sensory impairments may be missed when a diagnosis of schizophrenia or autism already has been made. The converse might also occur if the clinician attributes behavior to the sensory impairments such as in a child diagnosed as deaf-blind who might be deaf-autistic, blind autistic, or sensory impaired with intellectual disability. Ritualistic acts are common in severe or profound mental retardation as well as in childhood autism, and both rigidity of behavior and perseveration may characterize deafness or blindness, as well as mental retardation or autism. Typical deaf-blind individuals easily stop the rituals if offered human contact or interaction.

Treatment

Data on treatment of deaf-blind individuals with reactive or more serious psychopathology are woefully lacking. Behavior therapy, psychotherapy, and counseling may each be useful but are dependent on meaningful communication and development of a therapeutic relationship. The use of medication that could affect residual hearing or diminish visual perception should be avoided, but can be useful for symptomatic treatment to assist in daily living. The remarkable achievement of Helen Keller is instructive and inspiring, but is not a good model because she acquired a language foundation of both sight and sound prior to the onset of her

impairments. Some individuals who are deaf and blind fulfill their potential and lead competent lives. Deaf-blind youngsters who are aging out of the educational system often lack appropriate supportive services, including housing. There has been a shift in focus for adolescents to establish greater independence in the community rather than an abrupt transfer to adult rehabilitation facilities when they reach age 21.

Conclusion

Pivotal to the psychiatric evaluation and treatment of the child with hearing loss and/or blindness is understanding the influence and impact of the sensory loss(es) on both the developmental process and the presentation of psychiatric signs and symptoms. The deaf, blind, or deaf-blind child faces challenges learning about the physical and social world and him/herself in relation to others without the sensory information input readily available to typical peers, and in a world that is oriented to the needs of hearing and sighted people. The reality that many individuals with sensory-related losses lead successful and constructive lives is cause for optimism on the part of professionals and families that their efforts at enhancing the child's access to and interaction with their world can make a positive impact.

ACKNOWLEDGMENTS

The authors of this chapter wish to acknowledge Peter Hindley (4th Ed), Alison Salt (4th Ed), Stella Chess (3rd Ed) and Mayu PB Gonzalez (3rd Ed) who provided authorship to prior editions. Their contributions to the field of psychiatric care of deaf, blind and deaf-blind youth have been invaluable in advancing the evidence-based care to underserved communities.

CHAPTER 2.2.3 ■ SEXUAL MINORITY YOUTH: IDENTITY, ROLE, AND ORIENTATION

CYNTHIA J. TELINGATOR, ERIC N. BOYUM, AND PETER T. DANIOLOS

INTRODUCTION

The term sexual minority youth encompasses adolescents who are not exclusively heterosexual. It is challenging to write a chapter on sexual minority youth and avoid the trap of further entrenching a dichotomous discussion about sexuality, rather than advancing a discussion about the multidimensionality of an individual. Sexuality and gender are each complex entities which should be understood as being multidimensional, as well as individually experienced and expressed. Clinicians need to ask their patients about their experience in a developmentally sensitive manner in order to understand the meaning of these aspects of one's identity, and to help them to integrate their sexuality and gender with all the other aspects of their identity.

Sexual minority youth have joined with others who identify with a common label, such as "gay," "lesbian," "bisexual" to find acceptance and solidarity. Sexual minority youth across the country have lessened their isolation by finding community through the Internet and social media. These developments and other cultural influences have impacted young people who are increasingly resisting categorization. Creative and less rigid identity constructs have led to the development of new identities such as pansexual, polyamorous, and heteroflexible, to describe what has likely always been a more dynamic continuum of sexual experience and expression for individuals. In this chapter, we will use the term sexual minority to refer to youth with same sex attractions, relationships, or behaviors, regardless of their self-identification (1).

Although the categorization of gay, lesbian, and bisexual has been helpful in the past to find community, in many parts of the world it no longer is necessary to segregate oneself with others who label themselves in a similar way in order to find acceptance. Social change and the media have played an important role in redefining community for youth who are sexual minorities. Grassroots communities and school organizations such as Parents, Families, Friends, and Allies United with LGBTQ People (PFLAG), Gay, Lesbian, and Straight Education Network (GLSEN), and school-based Gay-Straight Alliances (GSA) have provided support to sexual minority youth, their families, friends and allies, irrespective of a youth's sexual identity. A decade ago, a *Washington Post*/Henry J. Kaiser Family Foundation/Harvard University sponsored survey noted that 57% of Washington, DC–area teens had a friend who is gay or lesbian (2). PFLAG now estimates that the rate is around 8 in 10 (3). The extensive media coverage, including social media, of

recent legal and sociocultural advances supporting gay, lesbian, bisexual individuals, youth, and families provides an affirming backdrop in which sexual minority youth and all youth can explore their identities. A good example of the power of social media is the "It Gets Better Project," which features gay and straight individuals, some of whom are celebrities and political leaders, sharing hope-filled messages for youth struggling with their sexuality. Whether through journalism, popular television, music, or films, there has been a growing visibility of sexual minority youth and adults who partner, have children, and create a home and a life outside of a heterosexual construct.

The variation in adolescent sexual identity development is as complicated as any aspect of identity development; social and cultural factors are clearly not the only determinants of sexual identity. The biologic, environmental, psychological, and sociocultural influences leading to divergent pathways of psychosexual development have not been fully worked out.

Stressors adolescents may experience might lead an adolescent and/or a family to seek psychiatric consultation. While the problems these adolescents face require the full empathy and support of a trained professional, it is important to acknowledge that not all sexual minority adolescents face these challenges with the same degree of severity. There are many recognized cases of individuals whom, for whatever reason, whether it is a solid support system, a loving environment, or their own abilities to maneuver the many complex challenges most adolescents in these stages of development face, are able to enter adulthood fully self-accepting and secure in their feelings regarding their sexual identity. Sexual minority youth, like their heterosexual peers, have strengths and vulnerabilities that may contribute to the development of various physical or mental health conditions. Most sexual minority youth will never come to the attention of a mental health clinician.

As child and adolescent clinicians, we often see the most vulnerable youth, whose circumstances overwhelm—but do not eliminate—their capacity for resilience. This vulnerability occurs secondary to complex interactions of the child within a family, culture, and society. Although research findings often find higher rates of mental health risk in adolescent sexual minority populations, it is difficult to isolate what is due to internalized homophobia and external stressors that sexual minority youth experience, versus other biologic and psychosocial factors. The defenses used to cope with both internal and external stressors can lead to compartmentalization to protect this aspect of one's identity from being known. Youth may consciously and unconsciously do this as a shelter from stigma and shame, from rejection by family or friends, or from emotional and physical harm by family members, peers and/or communities.

THEORETICAL CONCEPTUALIZATIONS

Although in the literature and in clinical discussion definitions may vary, some core concepts are defined here and used within the chapter.

While extensive discussion of gender is beyond the scope of this chapter and will be presented elsewhere in this textbook, gender and sexuality as aspects of identity coexist and therefore gender definitions will be briefly reviewed. *Gender role or expression* refers to culturally underwritten masculine and feminine behaviors, attitudes, and personality traits, partly biologically driven, and partly shaped by environment. "Aspects of sex-typed behavior in childhood and adulthood are affected by hormones that were present very early in development, confirming findings in other mammalian species" (p. 839) (4). This is often noticeable as early as age 2 or 3, although it can be flexible throughout the life cycle.

Gender identity refers to the youngster's internally perceived gender, regardless of chromosomal constitution, gonadal/hormonal secretions, or genitalia. Most children develop a stable gender identity that is concordant with their natal or assigned sex by around the age of 3. For some, gender-variant roles/expression in childhood may coincide with a later homosexual identity. Adult homosexual men recall gender nonconformity in early childhood more commonly than adult homosexual women, while the rate of recalled gender nonconformity in early childhood is very low among heterosexual adults (5). Similar results were found when comparing gender expression in home videos of children who identified as homosexual adults to those who identified as heterosexual adults, although the difference between men and women was not observed (6).

Distinct from gender role or identity, *sexual orientation* is the predominance of erotic feelings, thoughts, and fantasies one has for members of one, both, or neither sex. *Sexual identity* is one's personal identity as a sexual being, a label used by youth in regard to themselves, for example "gay," "lesbian," "queer," "pansexual," or "asexual." As Thompson and Morgan point out, "although we would typically expect (sexual orientation and sexual identity) to generally inform one another, this is not always the case" (p. 16) (7).

Some theorists have considered sexual orientation to be biologically driven, immutable, and stable categorical entities, resistant to conscious control (8–10). Contemporary theorists, such as Lisa Diamond, have considered a more multidimensional model of sexual development. Diamond and Savin-Williams demonstrated, for example, how older models derived primarily from gay male populations did not readily apply to female sexual minority youth. They found that the context for sexual identity development was more likely to be emotionally oriented for female adolescents and sexually oriented for male adolescents. Their findings challenged the generalization at the time that homosexual attractions and self-identification were developed primarily around sexual contact–finding it held true less often for female youth (11). This upheld what has become a leading theory that "[i]n contrast to (the paradigm developed for homosexual males), female same-sex

orientations often exhibit late and abrupt development, and inconsistencies among women's prior and current behavior, ideation and attractions have been extensively documented" (p. 1085) (12). Newer studies are beginning to include nonbinary descriptions of sexual orientation. For example, one study identified a group of predominantly women who identify as mostly heterosexual with some sexual minority aspects to their identities (13) and another identified a minority of individuals who display limited romantic feelings, attractions, or sexual behaviors toward either sex (14).

The idea of fluidity of sexual orientation is not limited to recent theorists. Sigmund Freud stated in *Analysis Terminable and Interminable* "We have come to learn, however, that every human being is bisexual in this sense and that his libido is distributed, either in a manifest or a latent fashion, over objects of both sexes" (pp. 211–253) (15). Kinsey first described a nonbinary understanding of sexual orientation as a spectrum with exclusive homosexuality on one end of a continuum and exclusive heterosexuality on the other. He found that for both men and women sexual behavior could be very fluid over time (16,17). Sexual orientation may not be within conscious control but may shift along a bisexual continuum for some, and for others remain in a fixed position.

In addition to sexual orientation, one's identity as a sexual minority can be malleable over time. Savin-Williams writes that sexual identity is most subject to conscious choice and thus fluid over time (8). Savin-Williams and Diamond posit that both sexual orientation and sexual identity exist along a continuum, with the possibility of a multitude of expressions over the lifespan of an individual. More recent research has identified some youth, particularly females, self-labeling as "mostly straight," adding to the diverse spectrum of sexual identity (7). Asexuality has become increasingly understood as a sexual orientation and identity. Although the meaning of this label can vary between individuals, most use it to denote an identity as someone who does not experience sexual attraction or desire, the need to engage in sexual behaviors, or the desire for romantic relationships with members of any sex (18).

Variability in the meaning of sexual orientation and identity can be related to a number of factors. Developmental stage is an important consideration. "The fluidity of sexual desire, behavior, and identity may be a fundamental characteristic of sexuality during the teenage years" (p. 323) (19). Shame and stigma, within cultural and social contexts, also play an important role with respect to both sexual orientation and sexual identity. For example, some African-American males take on a sexual identity known as "the Down Low," in which members typically self-identify as "straight" in daily life but may identify as "on the DL" with potential same-sex partners. Such males are often not in denial about bisexuality; rather, they face shame and stigma within the sexual minority community based upon their race, and within the African-American community based upon their sexual orientation (20,21). Joseph

Carrier wrote about the youth in Guadalajara, Mexico, where sexual orientation is defined differently, both by gender behavior and sexual practices. "Feminine males are especially denigrated because it is unthinkable that a masculine male could be a 'real homosexual.' Generally speaking, only male receivers in homosexual intercourse are considered 'homosexual.'" He also notes that "all people exhibiting traits of the opposite sex are considered to be homosexual" (p. 290) (22).

HISTORICAL OVERVIEW AND EPIDEMIOLOGY

Although the existence of divergent attractions and sexual behaviors is not a new phenomenon, public and professional discourse have changed over time. It was only in 1973 that homosexuality was deleted from the *Diagnostic and Statistical Manual* (from DSM II to DSM III) of the American Psychiatric Association, following the work of Evelyn Hooker that did not find increased rates of psychopathology among homosexuals (23). The Stonewall Rebellion in 1969, when the visibility of the gay, lesbian, bisexual, and transgendered community was increased in the media, had an influence as well. The social movement that began at that time has accelerated with the help of popular culture in the United States in recent years. Youth today are rejecting the labels that have served to help identify community in the past, and those who need or want to affix a label to themselves are sometimes choosing broader categories as mentioned earlier.

In 1992, Gary Remafedi et al. conducted a survey of Minnesota junior and senior high school students. Of the 36,706 students, 52% reported having some heterosexual experience and 1% as having had a homosexual experience. In this early study Remafedi found that 1.6% of males and 0.9% of females identified themselves as either bisexual or predominantly homosexual, and more than 10% were "not sure." Interestingly only 27.1% of the students with homosexual experience self-identified as homosexual or bisexual. He also found that even though a larger number of adolescent boys reported a homosexual identification, more adolescent girls reported same-sex attractions and fantasies (24). This does not necessarily correlate with assuming a gay, lesbian, or bisexual identity. In a 1998 study sample of Massachusetts students, when asked about same-sex experiences rather than self-labels, 6.4% of sexually experienced students reported same-sex sexual contact. In addition, they found that an equal number of male and female adolescents had same-sex experiences (25).

Some ongoing large national surveys, such as the National Health and Nutrition Examination Surveys (NHANES), National Survey on Family Growth (NSFG), and the Youth Risk Behavior Survey (YRBS) have included questions aiming to estimate the prevalence of aspects of sexual orientation and/or identity within the general population. In the 20 years since Remafedi's early study, the number of youth reporting same-sex sexual encounters has increased dramatically. Using NHANES

data, Liu et al. (26) found that 10.1% of females and 3.5% of males ages 14 to 19 reported at least one lifetime same-sex sexual partner. When adult respondents to the 1999 to 2012 NHANES surveys were categorized by 10-year birth cohorts, the rate of reporting a lifetime same-sex partner had doubled from the 1940 to 1949 cohort to the 1970 to 1979 cohort. Analysis of the NSFG data from 2002 to 2008 by Chandra et al. (27) yielded similar rates of same-sex experience as the NHANES data, around 11% for females and 2.5% for males age 15 to 19. Despite the increased reporting of same-sex sexual behavior over the past 20 years, the rates of adolescents reporting sexual minority identities in the 2005 to 2007 YRBS had increased only slightly from those observed by Remafedi in 1992, with 1.2% claiming a homosexual (gay or lesbian) identity, and 3.4% a bisexual identity (28). Similar to Remafedi's initial work, there was a low concordance between reported sexual identity and history of sexual behavior; only 21.4% of youth engaging exclusively with same-sex partners identified as a sexual minority, instead choosing to self-identify as heterosexual.

Data regarding traditional milestones in sexual orientation development were primarily developed through surveys of sexual minority youth involved in community programs. D'Augelli collected data in the late 1980s and again in the late 1990s in social and recreational programs for gay, lesbian, and bisexual youth in America and Canada. His final sample included 542 youths, 62% male, and 38% female. He found that 74% identified as gay or lesbian, and 20% reported being bisexual, but mostly gay or lesbian; and 6% said they were bisexual, but equally gay or lesbian and heterosexual. The bisexual group was significantly more represented by females. Notably, youth who identified as "bisexual but predominantly heterosexual" or "uncertain" were excluded from the sample. The sampled youth reported being aware of same-sex feelings around age 10 for males and age 11 for females. Self-labeling occurred on average 5 years after initial awareness. This is a significant decrease in the age that sexual minority youth are self-identifying from the literature of only a decade ago. More sexual minority youth are self-identifying while they are still of high school age and living at home even if they are not sexually active (19). D'Augelli found that even though society has become more accepting, "youths spent one-third of their lives aware of same-sex feelings but not revealing this to others" (19).

Floyd and Bakeman gathered data on a sample of 767 adult attendees of an LGBT festival in 2001, asking them to recall the age of certain milestones with respect to sexual orientation and identity development. They were able to compare milestone achievement between those who self-identified as a sexual minority before 1988, and after 1988. There was a change in both the age of disclosure of sexual orientation, which decreased over time from 20.7 to 17.9 years, and the period between self-identification and disclosure decreased from 6.1 years to 2 years (29).

Recent studies have shown that same-sex contact occurs a year or two prior to a boy's gay identification, while a girl is more likely to have her first same-sex contact

after identifying as lesbian. The context for first same-sex sexual contact and self-labeling was found to be more emotionally or relationship oriented for young women and sexually oriented for young men (11). Although the data on this has varied, it probably represents diverse trajectories that sexual minority youth take in their development (22,30,31). Many adolescents begin to explore their sexuality during this developmental period. While this is normative for heterosexual youth, sexual minority youth may not have this experience, due to stigma and internalized homophobia, which may delay the exploration of their sexuality (1).

Sexual minority youth face similar and different developmental tasks than their heterosexual peers as they try to assimilate this aspect of their identity into their lives and their social and emotional relationships. Adolescents who are raised in families and communities where heterosexuality is considered normative often hide or deny their same-sex feelings and interests. The implications of this for identity development are unknown. Since many of these teens are being raised in families where the parents have a different sexual orientation, it is difficult to make use of parental identifications or count on parental support to help with the process of self-exploration (32). Most minorities can at least look to parents who have experienced similar stigmatization due to shared group membership, with exceptions including deaf and hard of hearing youth who have hearing parents, or minority youth adopted by majority parents.

A study of youth ages 14 to 21 involved in sexual minority programming in Utah, of whom 48% indicated a Mormon/LDS religious affiliation, noted that over 10% of youth identifying as gay or lesbian had steadily dated someone of the opposite sex in the past year, and that 14.6% had had sexual intercourse with someone of the opposite sex in the past year. The rates of self-identified straight individuals engaging in same-sex dating was much lower. However, the data also suggested that the range of romantic and sexual expressions amongst gay–lesbian youth with their same-sex partners and straight youth with their opposite-sex partners were essentially no different. These data suggest that even within a generally nonaccepting sociocultural context, sexual minority youth might be pressured to try to “pass” by engaging in heterosexual relationships, but also build and explore same-sex relationships in the same way that heterosexual youth build and explore opposite-sex relationships (33). The degree to which involvement in accepting community programming, or having accepting family experiences, mitigated the nonaccepting sociocultural context was not examined in this study.

In his study, D’Augelli found that half of the sexual minority adolescent males and three-quarters of the adolescent females had had heterosexual experiences, with more females having had heterosexual sex prior to having a same-sex experience. More males (84%) than females (60%) in this study were aware of their same-sex feelings prior to engaging in heterosexual sex (19). Sexual identity, sexual behavior, and sexual orientation are not stable or necessarily congruent for many adolescents during

this period of development. This is particularly relevant for the mental health clinician who relies on the description of sexual behavior to define a patient's sexual orientation or sexual identity.

ADOLESCENT SEXUAL DEVELOPMENT

The development of sexual attractions, desires, behaviors, and self-identification is common among adolescents; yet, for both heterosexual and nonheterosexual youth these features of adolescent sexual development often are not stable and do not predict attractions, behaviors, or identities in adulthood (34). Currently, various models attempt to elucidate adolescent developmental pathways leading to sexual minority identities.

TABLE 2.2.3.1

TROIDEN'S STAGES OF HOMOSEXUAL DEVELOPMENT

Stage	Description	Period
1. Sensitization	A sense of feeling different from childhood peers, typically only reaching awareness in retrospect. Children feel inadequate in their natal gender roles, including not sharing interests with peers of the same gender and boys experiencing warmth in relation to other males that is recalled as atypical.	Childhood
2. Identity Confusion	The suspicion one might be homosexual begins to arise, based on same-sex attractions and behaviors. Culturally assumed and mandated heterosexual identity is threatened. Youngsters may cope by trying to pass as heterosexual and may engage in heterosexual sex to prove to themselves and others that they are heterosexual.	Early Adolescence
3. Identity Assumption	Gradually, one begins to self-identify as homosexual and identify oneself as homosexual to others, usually in the context of social contact with other homosexuals. Youth in this stage are particularly vulnerable to stigmatization. Rural and minority youth may have a much harder time due to lack of role models and double discrimination for the latter.	Variable, but typically late adolescence
4. Commitment	Finding harmony between emotional, romantic, and sexual aspects of one's homosexual identity. Past ambivalence gives way to belief of one's identity as "natural" and "normal." People in this stage no longer try to "pass" as heterosexual, though may continue to "cover their homosexuality from looming too large." There is increasing disclosure to peers and to family. Management of stigma shifts from the personal to political and educational efforts in the broader community.	Early Adulthood

Early models used a linear stage theory perspective to describe "milestones" that sexual minority youth reached in sequential order on their way to becoming self-accepting sexual minorities in adulthood. Using data from primarily adult self-identified gay males, Troiden, Cass, and others helped to begin a dialogue in the field about "normal" development for sexual minorities, describing a linear stage model of sexual identity development that depicts a pathway to complete integration of one's

sexual identity (Table 2.2.3.1) (10,35).

Contemporary theorists including Diamond, Garnets, Savin-Williams, Klein, and others have challenged these models of linear progression, and have introduced a multidimensional approach to sexual identity development (11,36,37). They critiqued earlier linear models for using male retrospective experiences as the norm, and not taking cultural factors into account (36,38). Diamond, for example, has argued that viewing sexual identity development in women as an evolving process may be more helpful in understanding their development with regard to both emotional and sexual attractions. In support of this, she showed that up to three quarters of self-identified sexual minority women had failed to progress linearly through Troiden's developmental stages, had experienced comparatively late and abrupt onset of development of same-sex attractions and had more often exhibited plasticity with respect attractions, behaviors, and self-identification (12,39). As Galatzer-Levy writes, "[i]n non-linear systems models, unlike epigenetic models, the fact that processes share initial and end points does not indicate that the paths joining these points are the same. Instead it leaves us free, in each case, to explore the path taken by the individual and suggests that there will often be multiple paths between various developmental points" (p. 432) (40). Fritz Klein developed the first alternative multidimensional model of sexual orientation, which includes a grid of seven variables: sexual attraction, sexual behavior, sexual fantasies, emotional preference, social preference, self-identification, and hetero/homosexual lifestyle, all plotted along a time course (11,16,17,41,42). Thus, these earlier linear models have given way to newer dimensional models of measuring how young people see themselves as sexual beings, regardless of sexual orientation (43).

Stigma and shame can deeply impact all aspects of human development, including that of sexual orientation and identity. Gay and lesbian youth who are consolidating their identities tend to use "impression management" skills, as described in the work of Goffman. His work has been expanded to help understand the experience of members of other stigmatized groups who use "covering" defenses to minimize the impact of stigma and the risk of rejection. Sexual minority youth do this by selectively disclosing to those most likely to be accepting, while minimizing disclosing to others aspects of their identity that they fear might lead to rejection. Goffman also described the process of "spoiled identities," as identity becomes reduced to the stigmatized aspects, denying membership in other aspects of the self, such as ethnicity and religious affiliation. This concept has been extended to sexual minority youth by authors such as Martin in his article *Learning to Hide: The Socialization of the Gay Adolescent*, and has been revisited by many others, including Yoshino's book on "covering" (44–46).

Some populations of sexual minorities have had significant struggles with respect to stigmatization. Rosario et al. looked at ethnic and racial differences in the coming-out process. They looked at a sample of Black, Latino, and white youths and found

that there were no significant differences in the achievement of sexual developmental milestones, sexual orientation, sexual behavior, or sexual identity between groups. They found that cultural factors did not impede the formation of identity but instead impacted identity integration. Cultural factors (which include religious beliefs) may delay integration of a gay identity, as manifested by limiting involvement in gay-related social activities, increasing discomfort related to self-disclosure, and increasing negative attitudes toward homosexuality (internalized homophobia) due to the impact being affiliated with a stigmatized group. They reported that Black sexual minority youth were involved in fewer gay-related social activities, reported less comfort with others knowing about their sexual orientation, disclosed their sexual orientation less frequently to others and had fewer positive attitudes toward homosexuality at baseline than did white youth. Despite being similar to white youth in other measures, Latino youths disclosed to fewer people than white youth. The investigators found that despite having fewer positive attitudes than their white counterparts at the outset of the study, Black youth reported greater increases in positive attitudes regarding their sexual identity than did white youths over time, and by the end of the study there was no difference between the groups (47). Other studies have similarly demonstrated that negotiating multiple identities impacts sexual minority identity formation in males and females of varied ethnic backgrounds (48–50). Subsequent research by Jamil et al. indicated that the development of racial and sexual identity occurred concomitantly in so-called "double minority" youth, referencing Black or Latino sexual minority adolescents that he studied. It was not uncommon that these youths experienced maltreatment related to both their emerging racial and sexual identities; "[p]articipants who experienced oppression in the home reported experiencing particularly high levels of distress" (p. 11) (51). They found that such youth utilized community-based sexual minority organizations and peers for support in the process of self-identification, while learning to "… successfully navigate gay, White, and ethnic communities as a (sexual minority) person of color" (pp. 11–12) (51). For some racial and ethnic groups, cultural prohibitions present barriers to the expression of one's sexual identity, while others permit it within a defined construct.

Although context has been studied to some extent with respect to stigma, some recent literature has looked more closely at the immediate (e.g., familial) and larger (e.g., cultural, historical) contexts in which young people are exploring their sexuality. Phillip Hammack has proposed a life course theory of sexual identity formation, taking stock of biological, social, cultural, and historical contexts of the coming-out process and how "… individuals construct their own life course through the choices and actions they take within the opportunities and constraints of history and social circumstances" (p. 269) (52,53). Emphasis is on the cultural, social, and historical context in which the young person is experiencing partly biologically based sexual attractions, romantic feelings, and desires. In this model, individuals with

same-sex attractions internalize social attitudes and identity labels, and make decisions about subsequent behavior based upon cultural possibilities and constraints. One ultimate goal of this line of research is to produce longitudinal narrative assessments of individuals to understand decision-making regarding sexual orientation and identity.

DEVELOPMENTAL CHALLENGES AND RESILIENCY

All adolescents face unique developmental challenges, heterosexual youth included, during this period of "storm and stress" (54). There has been debate in the literature about whether sexual minority youth are even more at risk. A growing number of studies has suggested this might be so for health risks (55), mental health symptoms (55–60), acting out (61), substance abuse (56,61), and suicidal thoughts and behaviors (56,57,59). Other investigators, however, have found similar rates of homosexuality in suicide victims to that of the general population (62), although some argue that difficulties in sampling and definitions of both suicidal events and sexual minority youth obscure these results (63).

Because of the evidence of a growing number of health disparities among sexual minorities, the Institute of Medicine (IOM) convened a panel to evaluate what is known about health status of sexual minorities, including sexual minority youth. The 2011 IOM report concluded that sexual minority youth indeed do face certain health disparities. Mental health and substance use disparities included increased rates of depression, suicidal behavior, and substance abuse. Suicidal behavior amongst sexual minority youth has been a concern for decades, though some have argued the risk has been overestimated. In 1989, the US government's report of the Secretary's Task Force on Youth Suicide showed that suicide was the leading cause of death among sexual minority youth. This report estimated that "up to" 30% of youth who committed suicide annually were sexual minorities. The author of this report went on to say that "… gay youth are 2 to 3 times more likely to attempt suicide than other young people" (64). Several private organizations convened an expert panel in 2007 to address the need for better understanding of suicide risk in sexual minorities, including sexual minority youth. They noted that sexual minority identification was more strongly predictive of suicide attempts in young males than in females, with the overall risk being 12% to 19% for males and less for females (65). After the IOM reviewed all available interim school-based, state-based, and national studies, the panel concluded that "… LGB youth and youth who report same-sex romantic attraction are at increased risk for suicidal ideation attempts, as well as depressive symptoms, in comparison with their heterosexual counterparts" (p. 147) (66). In addition to suicide, disproportionately high numbers of sexual minority youth have been found to use substances including tobacco, alcohol, and illicit drugs, with a younger age of first use compared to heterosexual youth. For unclear reasons,

bisexual female youth are at the highest risk of illicit drug use. Methamphetamine use among gay male youth is a concern, especially when combined with other risk behaviors in social contexts such as Internet-related sexual contacts or bathhouses (66). Because adolescents who self-identify as a sexual minority still at times engage with opposite sex partners, they are at the same or increased risk of teen pregnancy (66). New cases of human immunodeficiency virus (HIV) infection are disproportionately high for among males under 25 who have sex with other males—regardless of self-identification; in fact, sexual minority youth comprise 60% of new diagnoses of HIV infections for those under age 25 (66). Between 14% and 15% of young urban men ages 18 to 22 who have sex with men reported being HIV positive in a recent survey (67). Additionally, the IOM notes that young men who have sex with men are the only demographic group with an increasing incidence of HIV/AIDS diagnoses, particularly high among young African-American gay men (66,68). Female sexual minority youth are not immune to the increased risk of HIV infection; adolescent girls reporting sexual minority identity frequently have had sexual contact with an opposite-sex partner at some point and often engage in higher risk sexual contact (66).

Some sexual minority youth face external stressors and distress related to their sexual minority status that may lead them to face increased health risk factors, both physical and emotional, as well as increased health risk behaviors (69). Increased risk is related to both external and internal stressors. External stress has been defined in the literature as experiences of violence, verbal abuse, rejection, and other acts that are perpetrated against sexual minority youth or those who are assumed to be sexual minority youth (70,71). Although the causal link between external stressors, risk behaviors, and poor outcomes is not fully established, ongoing research suggests that much of the excess risk of depression and suicidal behavior, substance abuse, and sex risk behaviors in adolescence and young adulthood is attributable to rejection, bullying, and other forms of victimization (72–75). Adolescents who disclose a sexual minority identity to their parents may experience increased family conflict, as well as family rejection, particularly sexual minority males (76). Sexual minority youth are heavily overrepresented among homeless youth in the United States, with 22% to 35% of some samples of homeless youth being sexual minorities, with self-identified gay male youth being at highest risk (66,77). In one study of sexual minority youth, Margaret Rosario found that 48% reported being homeless at least once, a full half of those having been evicted from their home by a parent, at a mean age of 14 (78). Once homeless, sexual minority youth are much more likely to engage in a number of health risk behaviors and develop mental health problems (66). Physical and verbal harassment and victimization, unfortunately, are commonly faced by sexual minority youth in the community, at school, and at times in the home. A study done by D'Augelli looked at gay, lesbian, and bisexual self-identified youth at community centers during two periods: 1987 to 1989 and 1995 to 1997. There was

some geographic as well as cultural diversity in the sampling. He found that 81% of the 542 youths sampled reported verbal abuse related to being a sexual minority, 38% had been threatened with physical attacks, 22% had objects thrown at them, 15% had been physically assaulted, 6% had been assaulted with a weapon, and 16% had been sexually assaulted (19). All of these incidents were reported by the youth as being related to their sexual minority status. Some of this abuse occurred at school, some at home, and some in the community. Fear of being victimized was prevalent. Youth who were aware of their minority sexual orientation at earlier ages, self-identified earlier and self-disclosed earlier, reported more lifetime victimization. Some have reported that highly effeminate boys are targeted more than others as many have had atypical gender roles since childhood and have experienced social ostracism since an early age (79).

More recent retrospective data have been gathered on Adverse Childhood Events (ACEs) faced as youth by adult sexual minorities in comparison to their heterosexual peers, finding increased rates of verbal or physical abuse, physical or emotional neglect, household dysfunction, and school bullying (80). Both heterosexual and sexual minority men and women with gender nonconforming behaviors in childhood seem to be at increased risk of abuse, physical victimization, and emotional bullying, and later depression or PTSD symptoms (81,82).

Internal stress, plays a role in the excess risk of negative health outcomes for sexual minority youth, but the effect is less amenable to measurement and study. The internal stresses that sexual minority youth often face may shift, reflecting developmental factors at different life stages as well as different stages of the coming-out process, and tend to represent the internalization of society's negative attitudes toward homosexuality, termed *internalized homophobia* (83). In a case series of interviews retrospectively examining emotional angst faced in adolescence, Flowers and Buston describe a subject's account of distress through the coming-out process: "I remember going home at night and crying myself to sleep because I knew that I was different, and I was terrified of being different" (p. 54) (84). Another subject shared his experience of internalized homophobia: I felt different and yeah I suppose I knew I were gay, but I fought it, I really did fight it. Cos me mother is very very anti gay and me father is as well. I hated it. "I did not want to be gay, I did not want to be gay at all, ever. Because I, er, it made me an outcast. Everywhere I had to be constantly careful about what I did and I couldn't cope with it at all. I just didn't know about what to do or anything" (p. 55) (84). As Erik Erikson stated, "[t]he sad truth is that in any system based on suppression, exclusion, and exploitation, the suppressed, excluded, and exploited unconsciously accept the evil image they are made to represent by those who are dominant" (p. 445) (85). Newcomb and Mustanski completed a meta-analysis of over 5,800 adolescent and adult sexual minority subjects and found a small to moderate effect of internalized homophobia on depression and anxiety symptoms (86). As is the case for many minority populations,

stigma and shame play powerful roles in the lives and mental well-being of lesbian, gay, bisexual, and questioning youth. Gay youth often learn to hide their homosexual orientation by attempting to present themselves as heterosexual. This facade can become a process of deception at all levels, living a lie in order to obtain acceptance in their larger peer group, and keeping a protective distance from peers and parents from whom they hide their homosexuality (44). As might be expected, lower rates of self-disclosure are correlated with increased distress among sexual minorities (87). As put by a subject in the Flowers and Buston series: "I mean you can … pretend to be heterosexual as much as you like, but, when push comes to shove, … (it is difficult) to like create this big lie all the time, you know, live this lie, you lose it every so often" (p. 57) (84).

In 1994, prior to many of the more recent societal changes taking place that have supported a sexual minority identity, Savin-Williams wrote: "In actuality, the vast majority of gay male, bisexual, and lesbian youths cope with their daily, chronic stressors to become healthy individuals who make significant contributions to their culture" (p. 262) (88). Andrew Anderson studied 77 gay male youth in cross section, finding that at the time of the study over 80% were A and B students, most had high self-esteem, a good sense of social support, and a high sense of competency (89). A recent prospective study of the psychological adjustment of sexual minority youth into young adulthood found that psychological distress decreases significantly through adolescence, with the trend continuing into adulthood (73). Although the strength and resilience required to negotiate adolescence and reach self-acceptance of a sexual minority identity is important and complex, relatively little research has been done in this area. Protective factors—which include self-acceptance and acceptance by families, peers, and communities—were commonly noted in early literature on vulnerabilities faced by sexual minority youth, yet the importance of these protective factors has not fully been explored (90). Although much historical research focused on negative interactions between families and sexual minority youth, newer research is more optimistic about the innate capacity of a family to accept their sexual minority loved one, as well as adapt over time to become more accepting (91).

The focus of several investigations has been on how personal psychological factors of sexual minority youth impact their well-being and risk. A study by Lewis et al. found that lesbian adults who had lower levels of "stigma consciousness" had fewer negative psychological and physical outcomes (92). Lasser and Tharinger, extending the work of Bandura on social learning theory, noted that gay, lesbian, and bisexual youth utilized a strategy termed "visibility management" to negotiate their environment (93). This refers to how these youths make decisions about to whom to disclose what, and how to go about disclosing their sexual orientation. This is similar to the work of Goffman regarding "impression management" skills often found among stigmatized groups where individuals might attempt to tone down traits or personal features which lead to discrimination (94). Assessments of risk and

protection related to coping styles have consisted of cross-sectional studies to date, making the results hard to interpret since coping patterns in teenagers can change over time, sometimes in the face of stressors that sexual minorities often face (55,73,95).

Caitlin Ryan and her colleagues in the Family Acceptance Project have been working to understand the protection from risk afforded youth of generally accepting families (96). Sexual minority youth face a continuum of experiences including accepting, rejecting, or mixed behaviors and attitudes within a family, and the responses from parents and siblings may differ within each family.

Overall, the majority of sexual minority youth are well adjusted and not prone to health risk behaviors, mental health problems, suicide, or substance abuse and enter early adulthood as generally well-adjusted people. For some, "(the) experience of becoming gay (is) a difficult and painful journey of self-discovery and realization" (p. 60) (84). Scholar and psychoanalyst Galatzer-Levy, emphasizing that the vast majority of sexual minority youth emerge as healthy young adults, similar to their heterosexual peers, writes: "It is important that society as a whole come to terms with this new generation of well-adjusted, competent young men and women, who differ from their peers in terms of sexual orientation but little else" (p. 537) (97).

PSYCHOBIOLOGICAL THEORIES

Charlotte Patterson writes: "Is sexual orientation best thought of as an inborn characteristic determined by genetic factors? Or should it be regarded as socially constructed and malleable across the lifespan?" (p. 7) (98). The answer to this question is unknown. The development of a homosexual identity may be a complex and nonuniform interplay among genetics, in utero exposure to hormones, and neurodevelopmental, dynamic, and experiential factors. Given the breadth and fluidity of sexuality, one can theorize that there will never be a simple explanation for the development of sexual orientation (9,99–101).

Elevated concordance of homosexuality has been identified in several studies of identical male twins separated early in life and raised apart. Further, multiple twin studies have demonstrated that sexual orientation is highly heritable. Dean Hamer identified a sequence of markers at the tip of the X chromosome (Xq28) in 33 of 40 pairs of homosexual brothers; subsequent studies replicated this result, and also replicated that this finding is not present in lesbian twins (102). Recent attention has been paid to the genetics of female sexual orientation, gender nonconformity, and number of sexual partners, and found a heritable phenotype for homosexuality in women that provides evolutionary benefit, though no specific genetic locus was identified (101). While genes contributing to sexual orientation have not yet been discovered in humans, researchers are advancing further in determining genetic underpinnings of correlates in the fruit fly, *Drosophila melanogaster*. Early in

genetic research of the fruit fly, researchers identified a gene they named *fru* in males with variant alleles of this locus who chose not to mate with females, courted both males and females, elicited courtship from other males, and attempted to copulate with wild-type males. Over the ensuing 50 years, researchers have been further elucidating the ways in which alternative splicing of the mRNA produced by this gene leads to male-specific and female-specific versions of the protein (103). A breakthrough came in 2005 when investigators showed that by altering *fru* and a related gene *tra* they were able to affect sexual orientation, behaviors, and sex roles (104). The degree to which there is a genetic "master switch" for homosexual behavior in humans remains unclear, though heritability in twin studies and the early onset of behavioral differences in young children who grow up to be sexual minorities suggests a genetic framework for sexual orientation exists.

It has long been hypothesized that differences in hormone exposure play a role in the development of homosexuality in humans. While in adulthood there is no consistent difference in masculine or feminine sex hormones between exclusively heterosexual and nonheterosexual males and females, investigators are exploring the role of prenatal sex hormones in the development of structural differences in the brain and sex-linked behaviors in humans. Exposure of the fetus to testosterone at six to 12 weeks' gestation alters the neuronal migration in the hypothalamus, preoptic area, corpus callosum, planum temporale, cerebellum, and amygdala. Gorski described an area in the hypothalamus of rats, which he labeled the "sexually dimorphic nucleus," that is eight times larger in males than in females. This has led to studies on the hypothalamic nuclei of humans with respect to differences in these areas not only between males and females, but also between people of the same sex assigned at birth with different sexual or gender identities. While a Dutch group conclusively showed that sex difference in the human hypothalamic uncinate nucleus was related to gender identity rather than sex assigned at birth (105), the results for humans with different sexual orientations has been less consistent. In 1991, LeVay found that the hypothalamic nucleus (INAH-3) was two to three times larger in heterosexual men than in women and homosexual men, who had similarly sized nuclei, and postulated that this was linked to prenatal testosterone levels. Byne et al. also showed a consistent trend toward more female-typical INAH-3 volume in homosexual men (106). No study has conclusively linked prenatal hormone exposure to the variation in this brain region (100). Some additional differences in brain structures–the origins of which are unclear–have been found to exist between heterosexual and homosexual men. Such differences include corpus callosum anatomy, patterns of cerebral asymmetry, and connectivity between brain regions (100).

In summary, biologic theories of the development of sexual orientation—including genetic, prenatal hormonal, and neurodevelopmental theories—remain in the preliminary stages. The interplay between biologic framework and life experience of

sexual minority individuals has not yet been investigated. As Hines points out in her recent review on the role of hormones and sexual differentiation on gender and sexual orientation, " … social and cognitive developmental influences on children's activities could engage the same neural circuitry as underlies the effects of the early hormone environment," thus either synergizing with or reducing innate biologic influences on gender and sexual development (p. 81) (100).

EVALUATION AND INTERVENTION

There is no published or uniformly recommended evidence-based treatment strategy to assist youth with negotiating adolescence as a sexual minority youth (107). There is however a wealth of case based approaches, including family, psychodynamic, and cognitive-behavioral psychotherapeutic approaches, which have resulted in positive outcomes. This final section will review a range of recommendations for therapeutic approaches to sexual minority youth, their families, and—perhaps—their wider community. It is recommended that the reader also reference the current American Academy of Child and Adolescent Psychiatry's practice parameter on sexual minority youth.

The clinician should be aware of both the internal and external negotiations and compromises (reviewed in earlier sections of this chapter) that sexual minority youth need to face, and explore the adolescents' identity across the dimensions of emotional and physical attractions, intimate relationships, and behavior. The initial responsiveness and openness of the clinician will set the tone for the therapeutic encounter. Closed-ended questions will often foreclose on the possibility of developing trust and openness on the part of the sexual minority youth, as will a premature resolution of sexual identity. The patient is less likely to speak about same-sex attractions if the clinician assumes heterosexuality. Alternatively, identifying an adolescent with same-sex desires as gay or lesbian, without the adolescent labeling themselves as such, may prohibit exploration of other sexual orientations, identities, attractions or behaviors. The therapist can explore feelings that the adolescent is dealing with by creating a safe and nonjudgmental space. The adolescent is vulnerable to the internalization of the stigma associated with being a sexual minority youth, as detailed in earlier parts of the chapter. The therapist is similarly vulnerable both to impute stigma to the adolescent, and to feel stigmatized through the transference/countertransference interaction with the adolescent, possibly facilitated by projective identification. If he or she is unaware of this, it may impede both exploration and assimilation of this aspect of the patient's identity. Adolescents may not have conscious access to aspects of their sexual identity that are causing stress and emotional pain, but awareness may emerge through the creation of a safe therapeutic space. Dr. Hanley-Hackenbruck stated in her paper on *Coming Out and Psychotherapy* how "(g)iven that doctor and patient have society's attitudes in

common, homophobia will be both a transference and counter transference issue" (108). Unfortunately, this initial step of gaining therapeutic rapport can be difficult, with client, therapist, and contextual factors all contributing to whether adolescents will later find that the therapy experience was helpful (109).

As with any patient, the therapist should assess the adolescent's safety, with an awareness of the risk factors involved. This should include a mental status exam and substance use history. The clinician needs to assess the use of Internet pornography and sexually focused chat rooms, offering discussion and education about Internet predators. The clinician should review the potential for violence directed toward the patient. The clinician should also address the possibility of self-harm, including cutting, eating disorders, substance abuse, suicidal ideation, and risk. Assessment of unsafe sexual practices, known or suspected pregnancy and history of STI testing including HIV testing is recommended, with education and referral for additional evaluation if concerns arise. It is important to assess victimization in the home, school, and community. It is also valuable to explore the youth's perception of support from friends, parents, school and/or community-based organizations or online websites. Sexual minority youth may be aware of supportive resources, so open-ended questions are helpful in allowing youth to take the lead in navigating affirming programs, with further clinician supported investigation of local organizations such as GSA, GLSEN, Parents, Families, Friends, and Allies United with LGBTQ People.

In some cases, the psychiatrist may be asked by the patient, family, or both to consult with the youth's school. While maintaining confidentiality around the patient's and family's struggles, it is important in this situation to educate relevant school personnel regarding the risks of victimization and the important protective effect of support from teachers and staff at school.

Sexual minority youth are emotionally vulnerable due to questions and concerns about disclosing their sexual minority status and the possible consequences on their lives from family, peers, and/or institutions (87). Because of their fear of rejection, discrimination, and violence, they often hide this aspect of their identity from their parents, teachers, and other important adults. Sexual minority youth might disclose their sexual identity to a therapist, without the youth's family, friends, school, religious organization, or larger community being aware of it. The therapist is faced with tolerating anxiety about knowing a core part of their patient's identity, which may still be a secret from the parents. Many gay youths are conflicted as they discover that their sexual orientation does not coincide with their own dreams, or their families' hopes and dreams for their future, which are typically socially constructed with respect to a heterosexual paradigm. In their case series on young gay men's angst during the coming-out process, Flowers and Buston write of one young man's account: " … I used to have this idea … (that) by the time I was 23, I would be married with so many kids … but then I was still fancying lads" (pp. 55–56) (84).

The fear of needing to give up the fantasized future, causing psychic pain to themselves, as well as their parents, often contributes to the adolescent's decision to maintain this core aspect of their identity as a secret.

Internalized homophobia presents a significant challenge to the adolescent's psychological well-being, as referenced earlier in this chapter. Margolies, Becker, and Jackson-Brewer state in their paper *Internalized Homophobia: Identifying and Treating the Oppressor Within* that "[i]nternalized homophobia functions as a defense mechanism resulting from the ego's struggle between rules and desires. Rather than a single entity, internalized homophobia is comprised of a constellation of defense methods. Allowing for individual variations, the cluster usually includes rationalization, denial, projection, and identification with the aggressor" (pp. 229–242) (110). The form, intensity, and content of internalized homophobia will vary from adolescent to adolescent, and should be explored, in nonjudgmental terms, from genuine curiosity about the youth's experience (108). If the sexual minority identity of the patient is secret from the family, this binds the therapist and the patient together, but complicates work with the family. Bok speaks to the experience of secrets in psychotherapy (111), in which the therapist must remain mindful of both the protective and harmful aspects of secrets in a family. The therapist must respect the boundaries of confidentiality with the patient. When the adolescent wants to disclose his or her sexual identity to peers, siblings, and parents, the therapist may have a role in helping prepare their patient for the multitude of reactions he or she may face.

For some parents, their child's homosexual identity is experienced as a fundamental betrayal. Although still minimally represented in the literature, family accounts of their adolescent's coming-out process give valuable insight into parents' own beliefs, struggles, and capacity for acceptance. Parents' values are often part of the teenagers internalized value system, and both frequently derive from the larger sociocultural context in which the family lives. Not uncommonly, these values do not prepare a family to address such a revelation from their child in a healthy, accepting way. From her work with a community support group for parents of LGBT youth, Jessica Fields conducted in-depth parent interviews regarding their responses to their adolescents' disclosures about their sexual identities. Families commonly found that they did not have any "script" for handling the revelation and subsequent discussions about their child's sexual identity. "If people have been in a car accident we ask if they were hurt, how much damage there was to the car, whether or not it will be covered by insurance, [et cetera]. We had no script for this experience … " (p. 170) (112). Also, the parental fantasy about their adolescent's sexuality and sexual orientation is often infused with fantasies about their child's future relationships and creation of a family (113). This fantasy usually assumes heterosexuality, as "[s]exual orientation for gay men and lesbians is not recognized or acknowledged from birth, but is an achieved status rather than an ascribed status" (p. 437) (114). Recalling that some parents experienced the loss as similar to the

death of a child, Fields quotes one mother as having said: "(I am) grieving here. I feel as if I lost my son. I wanted him to get married, have children—I want grandchildren—a house. But now [that is] not going to happen. I have lost all of those dreams I had for my son, because (they are) not going to come true. (He is) never going to have a wife and kids and a house like I wanted him to" (112). Parents also worried that they genuinely had, or would be judged as having had, done something to affect their children's sexual development. One mother wondered whether aspects of her own marriage caused her daughter's development of a lesbian identity. A father worried if a lack of gender-typical play contributed to his son's sexual minority identity: "I was never good at sports, for one thing. I (did not) play much with him—play ball or anything like that. And (then) he was never too good at sports" (p. 172) (112). Another narrative study of parents by Erika Grafsky noted that families typically saw themselves as functional and healthy at the time of disclosure (115). Most commonly, the parents she interviewed indicated a high degree of stress or emotionality at the time of the disclosure, even including anticipatory anxiety by both adolescent and parent leading up to the disclosure. When describing her son asking her to pull the car over because he needed to tell her something, one mother said: "At this point, (I am) getting a little nervous … his eyes start to get misty and (I am) like, Oh God, (he has) got a girl pregnant … [a]nd then he just looks at me and out of his mouth comes, (I am) gay. When I get taken by surprise I start to turn red from my chest up and I could feel heat and redness just rising; (I cannot) tell if (he is) joking, (I cannot) tell if [he is] serious. And I look at him and then I see the tears in his eyes. He starts crying and I start crying and (I am) just like, '(that is) all you had to tell me?'" (p. 8) (115). Even after disclosure, most parents in this study experienced a significant amount of anxiety: "I was petrified. I thought somebody would hurt him, I mean, all the horrors of … people not accepting him. Is life [going to] be hard? Afraid of him being harassed at school. How do I tell people? How are people going to treat him?" (p. 9) (115). These narratives from families give the therapist important insights, but limitations include that both studies were primarily or exclusively of Caucasian families in the United States, giving limited insight to the experience of racial and cultural minorities, or patients from or in other countries. Additionally, these studies recruited primarily parents of young gay men, although attempts were made to recruit parents of all sexual minorities.

Family acceptance is vital not only to the youth's self-esteem but also to the youth's psychological well-being in the short and long term (96). Caitlin Ryan's Family Acceptance Project has been developed to educate and encourage families to engage in highly accepting behaviors toward their sexual minority sons and daughters, both at the time of and following disclosure. Through this work, it became apparent that even the majority of parents who are perceived as rejecting, or engage in rejecting behaviors, want to help their child and maintain family stability and are motivated by genuine care and concern for their child (91). The interventions include

a process of "meeting families where they are," similar to joining processes in other family therapy frameworks. This approach includes discussion of the overarching societal and cultural context in which the family lives, educating parents about the risks of family rejection, addressing common parent experiences of loss and shame, and addressing ongoing ambivalence and co-occurrence of accepting and rejecting behaviors by families (76,91,96). While the Family Acceptance Project does not yet have outcomes data as a health disparity intervention for sexual minority youth, the groundwork is promising.

For some families, the discovery of the adolescent's nonheterosexual orientation can lead them to want to change the young person's developmental trajectory, hoping that he or she might later assume a heterosexual identity, out of fear or misinformation that homosexuality is a mental disorder, or that the emergence of same-gender sexual desires among adolescents is abnormal or mentally unhealthy. While some programs propose to offer "conversion or reparative therapy" for sexual minority youth with this goal in mind, a recent report by the American Psychological Association reiterated previous denunciations of such sexual orientation change efforts. This report was supported by the American Academy of Pediatrics, American Psychiatric Association, the American Psychological Association, American Counseling Association, and the National Association of Social Workers (116). The United States Substance Abuse and Mental Health Services Administration (SAMHSA) released a report in October 2015 entitled "Ending Conversion Therapy: Supporting and Affirming LGBTQ Youth" (117). In this report, SAMHSA concludes that due to the significant risk of immediate and lasting harm to the young person, such sexual orientation change efforts are "inappropriate" (p. 26) (117). The most recent American Academy of Child and Adolescent Psychiatry practice parameter for working with sexual minority youth also states that "(c)linicians should be aware that there is no evidence that sexual orientation can be altered through therapy, and that attempts to do so may be harmful" (p. 967) (107). Thus, the consensus of the major mental health-related professional associations is that sexual orientation change efforts are strongly discouraged.

CONCLUSION

Due to massive and ongoing sociocultural shifts in many parts of the world, sexual minority youth increasingly have the opportunity to make life choices regardless of the gender of their partner(s), including marriage and having children. Here in the United States, the 2015 *Obergefell v. Hodges* Supreme Court decision affirming marriage as a right for all US citizens, not just heterosexual ones, has had a seismic impact (118). However, their path is complicated by the powerful forces of stigma, which can deeply impact their mental health, their core identity, and their sense of being a competent, "normal" sexual being, able to connect with others on an intimate

level. Mental health professionals can offer a safe space in which such youth can find acknowledgment, support, and fortification, allowing them to continue navigating their life-course. Self-acceptance and family support play important roles in the psychological well-being of these adolescents (59,96).

Sexuality is a core aspect of identity. Sexual identity emerges over time, impacted by biologic, familial, cultural, and environmental forces. For those whose identity outcome is not acceptable in their communities and families, development can be strained. In addition, with adverse circumstances, the overwhelming psychic burden may contribute to the development of symptoms of emotional illness and at times serious psychopathology. For some, resilience and other factors may minimize the emotional challenges sexual minority youth face with regards to their sexual orientation, and/or sexual identity. For others, the impact of stigma leads to even greater resilience and capacity. As culture shifts and transforms, formerly ostracized minorities are increasingly finding themselves to be accepted members of society. This has allowed more sexual minority youth to exist without the same pressures to develop "covering" defenses, or to "pass" as heterosexual, thus spared the negative psychological impact of turning to such dysfunctional strategies. However, many others do not have this freedom due to cultural, regional, ethnic, familial, religious and/or intrapsychic factors.

The role of the child and adolescent psychiatrist is to understand the child regardless of what self-labels are used and to assist the family with accepting their child's developmental trajectory. The clinician is in a unique position to facilitate the integration of a youth's sexuality with other aspects of their identity. The hoped-for outcome is the emergence of a child less "spoiled" by stigma, and less "reduced" to any one aspect of their identity, a person well equipped for the emotional growth needed to emerge as a complex and multidimensional individual.

2.3 DEVELOPMENTAL PSYCHOPATHOLOGY

CHAPTER 2.3 ■ DEVELOPMENTAL PSYCHOPATHOLOGY

SUNIYA S. LUTHAR

DEVELOPMENTAL PSYCHOPATHOLOGY DEFINED: MAJOR FEATURES

Developmental psychopathology is an integrative discipline, wherein principles from classical developmental theory are applied to investigate clinical and psychiatric phenomena (1–4). This integration of perspectives is invaluable because it promotes our understanding of atypical development and also illuminates understanding of normative developmental processes. To illustrate, applications of developmental theories such as those of Werner, Piaget, and Erikson provide critical insights into the organization and causes of different forms of maladjustment. Conversely, studies of pathology enhance our knowledge of normal development, particularly in terms of individual differences in development as well as risk and protective processes associated with different types of outcomes.

Whereas developmental and clinical psychology are integral elements in the field of developmental psychopathology, the scope of this integrative discipline extends beyond these areas. Theory and methods from these domains are integrated with those from various others, including epidemiology, biology, neuroscience, sociology, and anthropology. Such multidomain, multicontextual approaches to inquiry are essential in moving toward the long-term goal of a more comprehensive understanding of the development of psychopathology.

A final feature of developmental psychopathology is that it bridges the often wide span between empirical research and the application of knowledge, to benefit at-risk populations. Investigators in this tradition design and implement interventions that are based on developmental theory and research on risk and protective processes, such that they inform both preventive interventions and social policy.

To summarize, the four central characteristics that define the field of developmental psychopathology are (1) the use of classical developmental theory and research to inform issues of psychopathology, (2) the use of insights from at-risk or atypical populations to increase our understanding of normal developmental processes, (3) integration of developmental and clinical perspectives with those from other disciplines, and (4) the derivation of implications for preventive and therapeutic interventions, and for social policy.

RISK

In developmental psychopathology research, risk is defined in terms of statistical probabilities: A high-risk condition is one that carries high odds for measured maladjustment in critical domains (5). Exposure to community violence, for example, constitutes high risk given that children experiencing it reflect significantly greater maladjustment than those who do not (6). Similarly, maternal depression is a risk factor in that children of mothers with depressive diagnoses can be as much as eight times as likely as others to develop depressive disorders themselves by the adolescent years (7).

In addition to establishing discrete risk dimensions such as community violence, poverty, or parent mental illness, researchers have also examined composites of multiple risk indices such as parents' low income and education, their histories of mental illness, and disorganization in their neighborhoods. Seminal research by Rutter (8) demonstrated that when risks such as these coexist (as they often do, in the real world), effects tend to be synergistic, with children's outcomes being far poorer than when any of these risks existed in isolation. Use of this cumulative risk approach is well exemplified in work by Sameroff et al. (9,10). These authors computed a total risk score across 10 different dimensions, assigning for each one, a score of 1 (versus 0) if the child fell in the highest quartile of continuous risk dimensions, and for dichotomous dimensions such as single parent family status, if they were present in that child's life. An alternative approach, exemplified in work by Masten et al. (11), involves standardizing values on different risk scales and adding them to obtain a composite.

Decisions regarding the use of single- or multiple-risk indices in resilience research depend on the substantive research questions. The former is used, obviously, when applied researchers seek to identify factors that might modify the effects of particular environmental risks known to have strong adverse effects, so as to eventually derive specific directions for interventions. Examples are parental divorce or bereavement; knowledge of what ameliorates the ill effects of these particular adversities has been valuable in designing appropriate interventions (12,13). Additive approaches are more constrained in this respect, precluding identification, for example, of which of the indices subsumed in the composite are more influential than others. On the other hand, composite risk indices generally explain more variance in adjustment than do any of them considered alone, and as noted earlier, they may be more realistic in that many of these risks do co-occur in actuality (5,14).

Risk is rarely absolute; the potential for deleterious outcomes varies according to age as well as other child characteristics. Prolonged separation from the primary caregiver, for example, is more harmful for infants and toddlers than for older children, whereas community violence is less likely to affect preschoolers than older youth who are more able to move about the neighborhood independently. By the same token, there are some risks relatively unique to particular groups. An example is

racial discrimination, which affects ethnic minority groups but not children of Caucasian heritage.

The same construct can connote risk in one setting but be relatively benign or even beneficial in others. An example is stringency of parent discipline. Whereas high levels of control and strictness are often seen as deleterious for children, a series of studies have shown that they are actually beneficial for youngsters living in dangerous inner-city neighborhoods (15–18).

DISORDER

In developmental psychopathology as in child psychiatry, the notion of disorder often represents psychiatric diagnoses. Researchers typically assess diagnoses via structured interviews such as the Schedule for Affective Disorders and Schizophrenia for School-Aged Children (K-SADS-PL) (19) or the Diagnostic Interview Schedule for Children (NIMH DISC-IV) (20), which are usually administered to the child aged 5 and older as well as the primary caregiver. For each diagnostic category, these interviews have a series of initial probes to determine the existence of a disorder, and if responses are in the affirmative, then additional probes are asked to determine if diagnostic criteria are met.

The other approach, also commonly used, is to assess overall children's symptom levels on different maladjustment domains, via instruments such as the Behavior Assessment System for Children (BASC), (21) or the Child Behavior Checklist (CBCL) (22) (and its variants, the Teacher Rating Form [TRF] and the Youth Self Report [YSR] (23)). These measures include a list of symptoms from diverse maladjustment domains which collectively yield scores on discrete subscales (such as attention, conduct, or depressive problems); in turn, composite scores across related subscales indicate overall maladjustment, such as internalizing and externalizing symptoms (CBCL), or overall dimensions of behavior and personality (BASC).

Such dimensional measures have two major advantages; they capture a wide range of functioning and are very well normed. With regard to the first of these features, symptom scales such as the CBCL and BASC characterize children in terms of varying severity of dysfunction as opposed to simply the presence or absence of diagnoses. From a research standpoint, this is a major advantage because the greater the variance on a particular dimension, the more likely it is that it will show statistical links with other constructs (such as potential causes or ramifications of the symptoms). The issue of norms, similarly, is critical in gauging children's adjustment levels relative to those of the average child of the same age. Instruments such as the CBCL have been administered to thousands of children from all over the country (and world) and as a result, we know the average symptom levels on these. Typically, average levels of problems correspond to a T score of 50 with a standard deviation

of 10. Thus, if a child were to obtain a score of over 65 on the YSR, this would represent "much above average" dysfunction and a T score of 70 or more would indicate problems "very much above average."

Making such judgments about functioning vis-à-vis the average child is much more complicated with psychiatric disorders. There have been several large-scale epidemiologic studies on children's diagnoses, but there is some disagreement on rates of different disorders, with variations, for example, with the particular structured interview used. To illustrate, an NIMH study using the DISC reported that about 6% of adolescents suffer from depression (24), whereas a study using the K-SADS found the point prevalence to be 2.9% (25). At the same time, structured interviews remain the method of choice when the goal is specifically to assess the incidence of actual psychiatric diagnoses, rather than severity of symptoms.

A thorny problem in assessing childhood disorders—regardless of whether the approach involves diagnoses or symptom levels—is that there is considerable disagreement among respondents. The kappa statistic is commonly used to assess agreement across raters, with values above 0.75 representing high levels of agreement, values in the range from 0.40 to 0.75 representing moderate levels of agreement, and values below 0.40 representing low levels of agreement (26). In studies involving psychiatric diagnoses, agreement rates between parents and children have ranged from $k = 0.32$ for diagnoses of separation anxiety to $k = 0.22$ on diagnoses of general anxiety disorder to as low as $k = 0.17$ on ADHD (27, 28). Further demonstrating the disconnect between the child's and parents' understanding of the child's functioning, Roberts et al. (29) found that in measuring overall mental health, life satisfaction, happiness, and role strain, parent–child agreement was never above 0.20. On dimensional measures, similarly, the correlation between parents' reports and children's reports has ranged from $k = 0.02$ for anxious/depressed symptoms to $k = 0.14$ for delinquent behavior (30); there is generally more agreement among mother and father, but again, low consensus between parents and teachers (31).

Researchers have dealt with this disagreement in various ways. In the case of psychiatric diagnoses, a common approach is to use the "either/or" rule, assuming the child does in fact have a diagnosis if either the parent or the child indicates this is the case (32). An alternative strategy is by prioritizing adults' reports for some domains (conduct problems) and children's reports for others (depression), with the rationale that children are likely to underreport their own oppositional behavior, for example, or that parents are likely to know less about their child's inner life (33,34). Still others have separately considered parents' and children's reports, with the rationale that each reveals information not captured by the other (35–37).

A final comment about measurement of disorder: What is considered abnormal in one setting may be normative or even adaptive in another. This point is well illustrated in a paper by Richters and Cicchetti (38) entitled "Mark Twain meets

DSM-III-R: Conduct disorder, development, and the concept of harmful dysfunction, with regard to definitions of conduct disorders." The authors argue that many inner-city youth might meet DSM criteria for conduct disorders but in their own subculture, being able to defend themselves physically can be quite adaptive. Accordingly, they exhort additional consideration of the notion of "harmful dysfunction," put forth by Wakefield (39–41). Wakefield argued that the DSM definition of mental disorders fails to distinguish adequately an individual's negative reactions to his problematic environment from a "true" mental disorder, and that a mental disorder is best conceptualized as a harmful dysfunction, where harm is a value judgment regarding the undesirability of a condition, and dysfunction is the failure of a system to function as designed by natural selection. Anchored in notions of evolutionary design, Wakefield specifically defines a harmful dysfunction as the "harmful failure of an internal mechanism to perform a natural function for which it was biologically designed" (42).[1]

RESILIENCE

A salient construct in developmental psychopathology is resilience: a phenomenon or process reflecting relatively positive adaptation despite experiences of significant adversity or trauma. Inherent in this definition lie two fundamental conditions: significant risk (or adversity) and positive adaptation. Thus, resilience is never directly measured, but is indirectly inferred based on the evidence of the two subsumed constructs.

The notion of risk has already been discussed; positive adaptation, the second element in the construct of resilience, is defined as an outcome that is substantially better than what would be expected with respect to the risk circumstance being studied. In past studies of resilience across diverse risk circumstances, positive adaptation has been defined in terms of behaviorally manifested social competence, or success at meeting stage-salient developmental tasks (5,14,43). Among young children, for example, competence was operationally defined in terms of the development of a secure attachment with primary caregivers (44), and among older children, in terms of aspects of school-based functioning such as good academic performance and positive relationships with classmates and teachers (43,45).

In addition to being developmentally appropriate, indicators used to define positive adaptation must also be conceptually of high relevance to the risk examined in terms of both domains assessed and stringency of criteria used (46). When communities carry many risks for antisocial problems, for example, the degree to which children are able to maintain socially conforming behaviors is an appropriate indicator of success (47), whereas among children of depressed parents, the absence of depressive diagnoses would be of special significance (48,49). With regard to stringency of criteria, similarly, decisions must depend on the seriousness of the risks

under consideration. In studying children facing major traumas, it is entirely appropriate to define risk-evasion simply in terms of the absence of serious psychopathology (psychiatric diagnoses) rather than superiority or excellence in everyday adaptation (50).

Regardless of whether competence is described as risk evasion or positive adaptation, competence must be defined across multiple spheres. The multilevel measurement of competence, therefore, differs from the measurement of risk, which may legitimately involve one or multiple negative circumstances. Doing well in only one domain cannot be conceptualized as connoting resilience, as overly narrow definitions can fallaciously convey a picture of "success in the face of adversity." Adolescents, for example, might be viewed very positively by their peers but at the same time, perform poorly academically, or even demonstrate conduct disturbances (51,52), such that peer popularity by itself cannot be seen as an indicator of overall risk evasion.

The major focus of resilience researchers is to identify vulnerability and protective factors that might modify the negative effects of adverse life circumstances, and having accomplished this, to identify mechanisms or processes that might underlie associations found (5,53–55). While researchers have debated how to delineate such factors statistically (14,56), the conceptual definitions are fairly straightforward. Vulnerability factors or markers encompass those indices that exacerbate the negative effects of the risk condition while protective factors modify the effects of risk in a positive direction.

In some instances, it is more appropriate to define positive adaptation in terms of the family or community rather than necessarily of the child him or herself. As Seifer (57) has argued, because infants' and toddlers' functioning is often regulated by their caregivers, it can be more logical to operationalize positive adjustment in terms of the mother–child dyad or family unit rather than in terms of the young child's behavior. Similarly, there are times when the label resilience is most appropriate for communities of well-functioning at-risk youth. Research on neighborhoods, for example, has demonstrated that some low-income urban neighborhoods reflect far higher levels of cohesiveness, organization, and social efficacy than others (58,59), with the potential, therefore, to serve as important buffers against negative socializing influences.

FACTORS AFFECTING RESILIENCE AND VULNERABILITY

In discussions that follow, we overview major factors that contribute to relatively positive or negative outcomes among at-risk children. These factors fall into three broad categories: aspects of families, features of communities, and attributes of the children themselves.

Familial Factors in Resilience and Vulnerability

The critical importance of strong family relationships has been emphasized in various studies of resilience; a plethora of studies identify supportive and responsive parenting as being among the most robust predictors of resilient adaptation (5,8,54,56,60–64). In particular, early family relationships are extremely important in shaping long-term resilient trajectories. In their comprehensive review of the early childhood literature, Shonkoff and Phillips (65) emphasized that "[relationships] that are created in the earliest years … constitute a basic structure within which all meaningful development unfolds." Early experience places people on probabilistic trajectories of relatively good or poor adaptation, shaping the lens through which subsequent relationships are viewed and the capacity to utilize support resources in the environment. Thus, if early attachments are insecure in nature, at-risk children tend to anticipate negative reactions from others and can eventually come to elicit these; these experiences of rejection further increase feelings of insecurity (66–68). Conversely, at-risk children with at least one good relationship are able to take more from nurturing others subsequently encountered in development (44,65,67,69). The protective potential of strong family relationship has been demonstrated for mothers, fathers, and siblings (70,71).

Whereas early relationships are fundamental in shaping the lens through which people view their subsequent interactions, a "faulty lens" can be corrected to some degree. In general, developmental psychopathologists maintain that there is continuity and coherence in development so that positive adaptation in early years determines, in a probabilistic rather than determinative fashion, the likely success at later stages (44,72,73). At the same time, scholars recognize that lawful discontinuities often do occur, and in the context of attachment status, such changes frequently derive from modifications in the caregiving environment (73–76). Intervention studies provide consistent evidence with regard to the possibility of shifting attachment status, as seen in work by Heinicke and Dozier. In both sets of studies, children's insecure early attachments were remediated to some degree by intervention services that fostered caregivers' positive qualities including nurturance, responsiveness, and their own attachment states of mind (77–79).

In terms of what defines "good parenting," warmth and appropriate control are the two core constructs that are most important in children's relationships with their primary caregivers. Each factor has protective functions and the benefits of each depend to some degree on levels of the other: Both high warmth with lax discipline and strict discipline without affection can be linked with poor adjustment. The authoritative parenting style, characterized by the appropriate balance of parental warmth and control (80), is generally optimal; authoritative parents are defined as those who "… are warm, supportive, communicative, and responsive to their children's needs, and who exert firm, consistent, and reasonable control and close

supervision" (81).

In addition to warmth and control, limit-setting and monitoring are critical for resilient adaptation. Limit-setting refers to the use of appropriate rules and expectations in shaping socially desirable behavior in the child; the degree to which parents clearly define limits and consistently enforce rules is crucial in shaping the child's future compliance (82,83). Related to limit-setting and also important for resilient adaptation is the construct of parental monitoring, which is defined as a "set of correlated parenting behaviors involving attention to and tracking of the child's whereabouts, activities, and adaptations" (84). The salutary effects of consistent parental monitoring across various high-risk circumstances have been demonstrated from the elementary school years onward (85). The benefits of consistent parental monitoring are particularly pronounced among preadolescents and adolescents, who have increasing independence from parents and thus growing exposure to a host of risks in the peer and community environments. For example, a study of sixth graders with deviant peers showed that firm parental control inhibited the development of externalizing problems in later years (86–88).

Links between parent monitoring and adolescent adjustment are not always simple linear ones, but can depend on coexisting risks in the environment. To illustrate, Mason et al. (89) showed that in terms of ramifications for children's problem behaviors, optimal levels of control exerted by African-American parents varied according to negative influences in the community. When adolescents reported relatively high problem behaviors in their peer groups, for example, optimal levels of parental control tended to be higher than when children's peer problem behaviors were low. Regardless of circumstance, however, parental monitoring has emerged as a powerful construct in resilience research; in fact, among low-income 8 to 17 year olds, Buckner et al. (85) found that of several variables external to the child, only parental monitoring significantly differentiated resilient from nonresilient youths.

A relatively new construct related to limit-setting is parental "containment." Cavell (82) has emphasized the importance of an appropriate balance of warmth and discipline within the notion of parental containment, which is "any behavior that fosters in children a sense of restraint while not threatening their relationship security" (82). Recent studies have pointed to the protective potential of this construct. Building upon Cavell's (82) arguments on the significance of children's beliefs about the likelihood of being disciplined, Schneider et al. (83) defined perceived containment as the child's beliefs concerning the parent's capacity to enforce firm limits, and the likelihood that the parent will prevail in conflict. They found that children with a particularly strong sense of containment had mothers who applied effective discipline within the context of an emotionally positive relationship. Furthermore, high perceived containment was protective against externalizing behaviors as rated by parents and teachers (83).

The Importance of Genetic Factors

An interesting set of developments in the field of resilience is inquiry into the role of genetic contributions to vulnerability and protective mechanisms in the family, as is seen in research by Caspi et al. Two studies by this group identified specific genes implicated in protecting some maltreated children from developing psychopathology in adulthood. The first of these showed reduced likelihood of antisocial behavior in the presence of a genotype that confers high levels of the monoamine oxidase A enzyme (90), while the second study demonstrated that the likelihood of developing depression was lower in the presence of a genotype conferring the efficient transport of serotonin (91). Although the specific processes underlying the protective effects of such genetic factors are unknown, it is possible that they operate by shaping aspects of children's social–cognitive reactions to life stressors, as in their propensity to attributional biases, for example, or capacities for emotion recognition (92).

Further explicating the relationship between genetic factors and positive adaptation, a study by Kim-Cohen et al. (92) examined both genetic and environmental processes specifically within the resilience framework. The study involved an epidemiologic cohort of 1,116 twin pairs from low SES families. Two aspects of resilience were examined—behavioral and cognitive—and results of quantitative genetic models showed that additive genetic effects accounted for approximately 70% of the variation in children's behavioral resilience and 40% of the variation in cognitive resilience. Further analyses established protective effects of both maternal warmth and child's outgoing temperament, with each factor operating through both genetically and environmentally mediated effects.

A particularly critical conclusion drawn by these researchers, however, surrounds the implications for interventions: Heritability does not imply untreatability (93,94). As Kim-Cohen et al. (92) note, their study entailed "a genetically sensitive design (which demonstrated) that environmental effects can make a positive difference in the lives of poor children … Even child temperament promoted resilience through environmental processes." Of vital importance is their conclusion that if families confronting the myriad stresses of poverty are helped to move toward bestowing warm, supportive parenting, and providing stimulating learning materials, children can be helped to achieve greater behavioral and cognitive resilience.

Rutter (54,55) has outlined several important directions for future work involving gene–environment influences in resilience. Twin and adoptee studies of at-risk children can be used to (1) examine the relative contributions of genetic versus environmental influences in the ways that different protective and vulnerability factors operate; (2) uncover the mechanisms entailed in each of these (passive or active G–E mechanisms and critical influences underlying the environmental component); and (3) identify genetic markers that confer protection or vulnerability and better understand processes underlying their effects. Also needed are sibling

studies illuminating the relative contributions of shared versus nonshared, extrafamilial environments on different outcomes. Finally, genetics research can also contribute to new developments in the study of resilience through precise quantification of risk. As noted in the first section of this chapter, risk is generally inferred based on statistical links between aspects of the environment (maltreatment or poverty) and children's maladjustment, but this "measure" of risk is imprecise at best. With knowledge that some children have genes conferring liability to particular disorders, examining factors in the lives of those who do not succumb could contribute vastly to our understanding of processes in resilience.

Community Factors in Resilience and Vulnerability

In the community domain, a primary conclusion from extant resilience research is that ongoing exposure to community violence is highly inimical not only for children but also their parents and other adults (56). Among those who fear for their very lives, it is unrealistic to expect psychological robustness: When physical survival is threatened, all developmental tasks and processes are jeopardized. In the case of such risks, therefore, there must be priority on eradicating these experiences in whatever ways possible.

In addition to family-level protective markers, community-level factors can mitigate the effects that risks have on a child's development. Mentors and informal support networks can serve critical protective functions. Evidence in this regard is seen in the Big Brothers Big Sisters of America (BBBSA) movement, where volunteers interact regularly one on one with youth from single-parent homes, and supervision is provided on a monthly basis for the first year, then subsequently on a quarterly basis. Compared to their nonparticipating peers, BBBSA youth reported more positive academic behaviors, had better relationships with their parents and peers, and were 46% less likely to initiate illegal drug use, 27% less likely to initiate alcohol use, and 52% less likely to skip school (95). Other studies have demonstrated that salutatory experiences can derive from religious affiliations (96–98) and other forms of social support (99,100), demonstrating the powerful potential that community-level factors can have in promoting resilience in adolescents.

Additionally, there are several studies corroborating the protective functions of supportive relationships with teachers (101–103). Assessing more than 3,000 teacher–child relationships, Howes and Ritchie (104) found that in a sample of toddlers and preschoolers with difficult life circumstances, the quality of attachment with teachers was significantly related to measures of behavior problems as well as social competence with peers. Among a group of aggressive second and third graders, African-American and Hispanic students benefited more than did Caucasian students from supportive relationship with their teachers (105). Noting that minority

group students typically have lower access to positive relationships with school teachers, the authors suggested that they could be more responsive than Caucasians to supportive teachers when they are encountered (106). Finally, there are substantial benefits when classrooms reflect organized, predictable environments in which students participate in procedures governing their behaviors. Among African-American 7 to 15 year olds from low-income, mother-headed households, Brody et al. (87) demonstrated protective-stabilizing effects among children in such classrooms. Furthermore, positive classrooms were beneficial even when parent–child relationships were compromised as well as vice versa, indicating unique, significant contributions from both contexts in which children and adolescents spend appreciable amounts of time (87,107).

Individual Factors in Resilience and Vulnerability

Salient protective and vulnerability processes affecting at-risk children can occur not only at the familial and community level, but at the child level. For example, male gender can be a vulnerability marker among youth living in the ecology of urban poverty, as boys are typically more reactive than girls to negative community influences (108,109). In addition, lower levels of intelligence can act as a vulnerability factor in that among children experiencing severe and chronic life adversities, those with low intelligence are more vulnerable to adjustment difficulties over time than are others (5). Similarly, some personal attributes are linked with relatively positive outcomes among children facing adversities, such as internal locus of control (beliefs that events in one's life are largely determined by one's own efforts rather than by luck or chance) or feelings of self-efficacy (5,110–112). Studies have also suggested the protective potential of emotional intelligence, the ability to perceive and express emotions, to understand and use them, and to manage them to foster personal growth (113,114). Among adolescents, emotional intelligence is linked with relatively low likelihood of smoking cigarettes and drinking alcohol (115) and following the major life transition to beginning college, with greater likelihood of attaining high academic grades (116).

A critical caveat regarding "protective individual attributes" such as internal locus of control or intelligence is that they themselves are not fixed or immutable, but are highly influenced by the external environment. To consider intelligence as an example, Koenen et al. (117) have shown that even after controlling for genetic factors and externalizing and internalizing problems, exposure to domestic violence accounted for significant variation in children's IQs. Therefore, individual factors in resilience and vulnerability must be considered in relation to the environments in which they originate and operate.

Acknowledging the continued malleability of individual traits (especially among younger children), Luthar and Zelazo (56) argued that in considering the triad of

protective and vulnerability factors in resilience, children's own attributes should be considered after aspects of their families and communities for three major reasons. From a basic research perspective, numerous studies have shown that many positive child attributes are themselves often dependent on processes in the proximal and distal environments. From an applied perspective, it is logical that interventions to foster resilience should focus less on what young children are able to do for themselves, and more on what adults must do to bolster the children's own efforts. From a policy perspective, finally, to place primary emphasis on child attributes could carry the risk that public debate will shift away from the major environmental risks that affect children, leading to decreased allocation of resources to ameliorate these risks (14,56).

Biologic Factors

The previous examples—like most of resilience research thus far—generally encompass psychological variables; also useful in scientific studies has been consideration of biologic indices, again, both as mediators of risk itself and as processes underlying vulnerability and protective factors (118,119). In terms of protective processes, the capacity to regulate or modulate negative emotions in the face of threats is of obvious importance for managing well in inauspicious situations (85,120,121) and here again, biologic processes can be salient. First, the capacity to recover relatively quickly from negative events experienced may be gauged by studying the startle reflex, which is a biologic and involuntary response (a fast twitch of facial and body muscles) to a sudden and intense visual, tactile, or acoustic stimulus (122). Studies have shown that adverse environmental influences not only affect the startle reflex, but the neural network that underlies this response (123). A second biologic mechanism that might be implicated is neuroendocrine in nature. Chronic exposure to stressful experiences tends to lead to excessive activation of the hypothalamic–pituitary–adrenal (HPA) axis, causing hypercortisolism, or elevations in the stress hormone cortisol. Hypercortisolism can result in pathogenic effects on neurons (124,125) and changes in the synthesis and reuptake of neurotransmitters and density of sensitivity of receptors (126,127). These findings point to the possibility that resilient individuals can be described in a neuroendocrine manner as those who, in the face of various stressors, tend to return relatively quickly to baseline levels of neuroendocrine functioning, and thus avoid the damage conferred by hypercortisolism.

SUMMARY OF EVIDENCE AND IMPLICATIONS FOR THE FUTURE

In concluding a review of almost half a century of work on resilience, Luthar

summarized the major take-home message thus: “Resilience rests, fundamentally, on relationships. The desire to belong is a basic human need and positive connections with others lie at the very core of psychological development; strong, supportive relationships are critical for achieving and sustaining resilient adaptation” (128). The childhood years have emerged as especially significant, as a child’s relationship with his or her primary caregiver forms a lens through which future interactions are interpreted. As a result, early attachments influence numerous nascent psychological attributes and the negotiation and resolution of major developmental tasks, and in turn, the likelihood of success at future tasks. Thus, serious disruptions in the early relationships with caregivers, whether in the form of physical, sexual, or emotional abuse, severely impair the chances of resilient adaptation later in life. On a more positive note, secure and healthy relationships with those in one’s proximal circle act as invaluable protective processes, for children as well as adults (129). Over the years, “good relationships” have been conceptualized in terms of two broad components—warmth and support on the one hand, and appropriate control or discipline on the other. A central direction for interventions, therefore, is to foster the development and sustenance of positive parenting patterns among parents in high-risk circumstances. Additionally, there must be attention to the specific relationship ingredients that are particularly influential or important within the context of particular types of risk; in neighborhoods rife with community violence, for instance, strategies to ensure physical safety are clearly of unique importance.

While resilience research has labeled various community-level risk factors, the community can also be an important source of support when the child’s own parents are constrained in this regard. High-quality child care is particularly valuable for children in the most at-risk families, as strong, supportive relationships with teachers can be highly beneficial for school-age children and adolescents. There is great potential to use K–12 schools as venues to foster resilient adaptation. Thus far, several school-based interventions based on social control and social learning theories—involving teachers as well as parents—have shown some success in randomized trials. Attachment-based interventions, where the emphasis is on developing close, supportive bonds with the teacher, have been insufficiently examined in school settings, though the positive effects of such programs are potentially far reaching. In addition to school-based initiatives, support provided by informal mentors (as in Big Brothers, Big Sisters) can serve important protective functions, especially when the relationships are of relatively long duration. Involvement in religion, similarly, can confer benefits via the availability of a stable support network and the promotion of relatively positive coping strategies. At the neighborhood level, cohesion and shared supervision of children are important positive influences, as is high participation in local and voluntary organization. Children benefit from participation in structured extracurricular activities, but unstructured settings (as in youth recreation centers) can exacerbate risks.

In terms of children's personal attributes, research on biological processes that confer significant vulnerability can be very useful for psychopharmacological interventions. Just as the environment sets confidence limits within which biology determines functioning, biology sets limits within which the environment determines adaptation levels. If a chemical imbalance in the brain predisposes a child or adolescent to depression, the threshold of tolerance to environmental stressors becomes considerably lower so that even stressors of moderate severity could precipitate a debilitating depression; awareness of such biologic vulnerabilities, therefore, is important for gaining complete understandings of risk exposure and positive adaptation. Even as we strive to promote the quality of children's family and community environments, careful pharmacologic interventions targeting the biology involved in psychiatric disorders—particularly among youth at high genetic risk by virtue of parent mental illness—will be critical in maximizing resilient adaptation among children and adolescents at high risk.

ACKNOWLEDGMENT

---

[1]Subsequently, this notion has been criticized by some others. Lilienfield and Marino (1995), for example, argue that many mental disorders are not, as Wakefield claims, evolutionary adaptations but rather neutral byproducts of adaptation; they believe that Wakefield's sociobiological definition of disorder is too narrow in its conceptualization. Murphy and Woolfolk (2000) critique Wakefield's view from a different angle, arguing that it fails to account for those disorders that are not a result of malfunction and those disorders whose causes have no adaptive function.

SCIENTIFIC FOUNDATIONS

3.1 RESEARCH METHODOLOGY

CHAPTER 3.1.1 ■ UNDERSTANDING RESEARCH METHODS AND STATISTICS: A PRIMER FOR CLINICIANS

GEORGE A. MORGAN, JEFFREY A. GLINER, AND ROBERT J. HARMON

INTRODUCTION

Purposes of Research

Research has two general purposes: (a) increasing knowledge within the discipline and (b) increasing your knowledge as a professional consumer of research in order to understand and evaluate research developments within your discipline. For many clinicians, the ability to understand research in one's discipline may be even more important than making research contributions. Dissemination of research occurs through an exceptionally large number of professional journals, workshops, and continuing education courses, as well as popular literature. Today's professional cannot simply rely on the statements in newspapers or of a workshop instructor to determine clinical practice. Even journal articles need to be scrutinized for weak designs, inappropriate data analyses, or incorrect interpretation of these analyses. Clinicians must have the research and reasoning skills to be able to make sound decisions. This chapter is intended to help clinicians be critical readers of the research literature.

Research Dimensions and Dichotomies

Self-Report Versus Researcher Observation

In some studies the participants self-report to the researcher about their attitudes, intentions, or behavior. In other studies the researcher directly observes and records the behavior of the participant. Sometimes instruments such as heart rate monitors are used by researchers to "observe" the participants' physiologic functioning. Self-reports may be influenced by biases such as the halo effect, or participants may have forgotten or not thought about the topic. Many researchers prefer observed behavioral data. However, sensitive, well-trained interviewers may be able to alleviate some of the biases inherent in self-reports.

Quantitative Versus Qualitative Research

We believe that this topic is more appropriately thought of as two related dimensions. The first dimension deals with philosophical or paradigm differences

between the quantitative (positivist) approach and the qualitative (constructivist) approach to research (1). The second dimension, which is often what people mean when referring to this dichotomy, deals with the type of data, data collection, and data analysis. We think that, in distinguishing between qualitative and quantitative research, the first dimension is the most important.

Positivist Versus Constructivist Paradigms. Although there is disagreement about the appropriateness of these labels, they help us separate the philosophical or paradigm distinction from the data collection and analysis issues. A study could be theoretically positivistic, but the data could be subjective or qualitative. In fact, this combination is quite common. However, qualitative data, methods, and analyses often go with the constructivist paradigm, and quantitative data, methods, and analyses are usually used with the positivist paradigm. This chapter is within the framework of the positivist paradigm, but the constructivist paradigm provides us with useful reminders that human participants are complex and different from other animals and inanimate objects.

Quantitative Versus Qualitative Data, Data Collection, and Analysis. Quantitative data are said to be “objective,” which indicates that the behaviors are easily and reliably classified or quantified by the researcher. Qualitative data are more difficult to describe. They are said to be “subjective,” which indicates that they are hard to classify or score. Some examples are perceptions of pain and attitudes toward therapy. Qualitative/constructivist researchers usually gather these data from interviews, observations, or documents. Quantitative/positivist researchers also gather these types of data but usually translate such perceptions and attitudes into numbers. Qualitative researchers, on the other hand, usually do not try to quantify such perceptions; instead, they categorize them and look for themes.

Data analysis for quantitative researchers usually involves well-defined statistical methods, often providing a test of the null hypothesis. Qualitative researchers are more interested in examining their data for similarities or themes which might occur among all of the participants on a particular topic.

VARIABLES AND THEIR MEASUREMENT

Research Problems and Variables

Research Problems

The research process begins with a problem. A research problem is an interrogative sentence about the relationship between two or more variables. Prior to the problem statement, the scientist usually perceives an obstacle to understanding.

Variables

A variable must be able to vary or have different values. For example, gender is a variable because it has two values, female or male. Age is a variable that has a large number of potential values. Type of treatment/intervention is a variable if there is more than one treatment or a treatment and a control group. However, if one studies only girls or only 12-month-old infants, gender and age are not variables; they are constants. Thus, we define a *variable* as a characteristic of the participants or situation that has different values *in this study*.

Operational Definitions of Variables

An operational definition describes or defines a variable in terms of the operations used to produce it or techniques used to measure it. Demographic variables like age or ethnic group are usually measured by checking official records or simply by asking the participant to choose the appropriate category from among those listed. Treatments are described in some detail. Likewise, abstract concepts like mastery motivation need to be defined operationally by spelling out how they were measured.

Independent Variables

We do not restrict the term *independent variable* to interventions or treatments. We define an independent variable broadly to include any predictors, antecedents, or *presumed* causes or influences under investigation in the study.

Active Independent Variables. An active independent variable such as an intervention or treatment is *given* to a group of participants (experimental) but not to another (control group), within a specified period of time *during* the study. Thus, a pretest and posttest should be possible, even if not actually used.

Attribute Independent Variables. A variable that could not be manipulated is called an *attribute independent variable* because it is an attribute of the person (e.g., gender, age, and ethnic group) or the person's usual environment (e.g., abuse). For ethical and practical reasons, many aspects of the environment cannot be manipulated or given and are thus attribute variables. This distinction between active and attribute independent variables is important for determining what can be said about cause and effect. Research where an apparent intervention is studied after the fact is sometimes called *ex post facto*. We consider the independent variables in such studies to be attributes, and they do not justify cause and effect conclusions.

Dependent Variables

The dependent variable is the outcome or criterion. It is assumed to measure or

assess the effect of the independent variable. Dependent variables are scores from a test, ratings on questionnaires, or readings from instruments (electrical diagram). It is common for a study to have several dependent variables (performance and satisfaction).

Extraneous Variables

These are variables that are not of interest in a particular study but could influence the dependent variable and need to be controlled. Environmental factors, other attributes of the participants, and characteristics of the investigator are possible extraneous variables.

Levels of a Variable

The word *level* is commonly used to describe the values of an independent variable. This does not necessarily imply that the values are ordered. If an investigator was interested in comparing two different treatments and a no-treatment control group, the study has one independent variable, treatment type, with three levels, the two treatment conditions and the control condition.

We have tried to be consistent and clear about the terms we use; unfortunately, there is not one agreed-upon term for many research and statistical concepts. At the end of most sections, we have included a table, similar to Table 3.1.1.1, that lists a number of key terms used in this chapter alongside other terms for essentially the same concept used by some other researchers. In addition to these tables of different terms for the same concept, we have appended a list of partially similar terms or phrases (such as independent variable vs. independent samples) which do not have the same meaning and should be differentiated.

Measurement and Descriptive Statistics

Measurement

Measurement is introduced when variables are translated into labels (categories) or numbers. For statistical purposes, we and many statisticians (2) do not find the traditional scales of measurement (nominal, ordinal, interval, or ratio) useful. We prefer the following: (a) *dichotomous* (a variable having only two values or levels), (b) *nominal* (a categorical variable with three or more values that are not ordered), (c) *ordinal* (a variable with three or more values that are ordered, but not normally distributed), and (d) *normally distributed* (an ordered variable with a distribution that is approximately normal [bell-shaped] in the population sampled). This measurement classification is similar to one proposed by Helena Chmura Kraemer (personal communication, March 16, 1999).

TABLE 3.1.1.1

SIMILAR RELATED TERMS ABOUT VARIABLES

- Active independent variable ≈ manipulated variable ≈ intervention ≈ treatment
- Attribute independent variable ≈ measured variable ≈ individual difference variable
- Dependent variable (DV) ≈ outcome ≈ criterion
- Independent variable (IV) ≈ antecedent ≈ predictor ≈ presumed cause ≈ factor
- Levels (of a variable) ≈ categories ≈ values ≈ groups ≈ samples

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right.

Descriptive Statistics and Plots

Researchers use descriptive statistics to summarize the data from their samples in terms of frequency, central tendency, and variability. Inferential statistics, on the other hand, are used to make inferences from the sample to the population.

Central Tendency. The three main measures of the center of a distribution are mean, median, and mode (the most frequent score). The *mean* or arithmetic average takes into account all of the available information in computing the central tendency of a frequency distribution; thus, it is the statistic of choice if the data are normally distributed. The *median* or middle score is the appropriate measure of central tendency for ordinal level data.

Variability. Measures of variability tell us about the spread of the scores. If all of the scores in a distribution are the same, there is no variability. If they are all different and widely spaced apart, the variability is high. The *standard deviation* is the most common measure of variability, but it is appropriate only when one has normally distributed data. For nominal/categorical data, the measure of spread is the number of possible response categories.

Normal Curve

The normal curve is important because many of the variables that we examine in research are distributed in the form of the normal curve. Examples of variables that in the population fit a normal curve are height, weight, IQ, and many personality measures. For each of these examples, most participants would fall toward the middle of the curve, with fewer people at each extreme.

As shown in Figure 3.1.1.1, if a variable is normally distributed, about 68% of the participants lie within one standard deviation from either side of the mean, and 95% are within two standard deviations from the mean. For example, assume that 100 is the average IQ and the standard deviation is 15. The probability that a person will have an IQ between 85 and 115 is 0.68. Furthermore, only 5% (0.05) would be expected to have an IQ less than 70 or more than 130. It is important to be able to

conceptualize area under the normal curve in the form of probabilities because statistical convention sets acceptable probability levels for rejecting the null hypothesis at 0.05 or 0.01.

Conclusions about Measurement and the Use of Statistics

Table 3.1.1.2 summarizes information about the appropriate use of various kinds of plots and descriptive statistics, given nominal, dichotomous, ordinal, or normal data. Statistics based on means and standard deviation are valid for normally distributed (normal) data. Typically, these data are used in the most powerful statistical tests, for example, analysis of variance, these statistical tests are called parametric statistics. However, if the data are ordered but grossly nonnormal (ordinal), means and standard deviations may not give meaningful answers. Then the median and a nonparametric test based on rank order would be preferred. Nonparametric tests have less power than parametric tests (they are less able to reject the null hypothesis when it should be rejected), but the sacrifice in power for nonparametric tests based on ranks usually is relatively minor. If the data are nominal (unordered), one would have to use the mode or frequency counts. In this case, there would be a major sacrifice in power. It would be misleading to use tests that assume the dependent variable is ordinal or normally distributed when the dependent variable is, in fact, nominal/not ordered. Table 3.1.1.3 provides examples of potentially confusing, essentially equivalent terms about measurement and descriptive statistics.

Measurement Reliability

Measurement reliability and measurement validity are two parts of overall research validity, the quality of the whole study. Reliability refers to consistency of scores on a particular instrument. It is incorrect to state that a test is reliable because reliability takes into account the sample that took the test. For example, there may be strong evidence for reliability for adults, but scores of depressed adolescents on this test may be highly inconsistent. When researchers use tests or other instruments to measure outcomes, they need to make sure that the tests provide consistent data. If the outcome measure is not reliable, then one cannot accurately assess the results.
FIGURE 3.1.1.1. Frequency distribution and areas under the normal and standardized curve.

TABLE 3.1.1.2

SELECTION OF APPROPRIATE DESCRIPTIVE STATISTICS AND PLOTS

	Nominal	Dichotomous	Ordinal	Normal
Graphic Depiction (Plot)				
Frequency Distribution	Yes[a]	Yes	Yes	OK[b]
Bar chart	Yes	Yes	Yes	OK
Histogram	No[c]	No	OK	Yes
Frequency polygon	No	No	OK	Yes
Box and whiskers plot	No	No	Yes	Yes
Central Tendency				
Mean	No	OK	Of ranks, OK	Yes
Median	No	OK = mode	Yes	OK
Mode	Yes	Yes	OK	OK
Variability				
Range	No	Always 1	Yes	Yes
Standard deviation	No	No	Of ranks, OK	Yes
Interquartile range	No	No	OK	OK
How many categories	Yes	Always 2	OK	Not if truly continuous
Shape				
Skewness	No	No	Yes	Yes

[a] *Yes* means a good choice with this level of measurement.
[b] OK means OK to use, but not the best choice at this level of measurement.
[c] No means not appropriate at this level of measurement.

Conceptually, reliability is consistency. When evaluating instruments it is

important to be able to express reliability numerically. The correlation coefficient, often used to evaluate reliability, is usually expressed as the letter r, which indicates the strength of a relationship. The values of r range between −1 and +1. A value of 0 indicates no relationship between two variables or scores, whereas values close to −1 or +1 indicate very strong relationships between two variables. A strong positive relationship indicates that people who score high on one test also score high on a second test. To say that a measurement is reliable, one would expect a coefficient between +0.7 and +1.0. Others have suggested even stricter criteria. For example, reliability coefficients of 0.8 are acceptable for research, but 0.9 is necessary for measures that will be used to make clinical decisions about individuals. However, it is common to see published journal articles in which one or a few reliability coefficients are below 0.7, usually 0.6 or greater. Although correlations of −0.7 to −1.0 indicate a strong (negative) correlation, they are totally unacceptable as evidence for reliability.

TABLE 3.1.1.3

SIMILAR TERMS ABOUT MEASUREMENT

- Categorical variable ≈ usually nominal, but variables may have discrete ordered *categories*
- Dichotomous ≈ binary ≈ dummy variable ≈ nominal with two categories
- Interval scale ≈ numeric ≈ continuous variable ≈ quantitative ≈ scale data
- Mean ≈ average ≈ arithmetic average
- Median ≈ midpoint
- Normal ≈ (approximately) normally distributed variable ≈ interval and ratio data ≈ quantitative ≈ continuous
- Nominal scale ≈ unordered categorical variable ≈ qualitative ≈ discrete
- Ordered variable ≈ ordinal or interval scale
- Ordinal scale ≈ unequal interval scale ≈ discrete ordered categorical variable
- Range ≈ spread

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right.

There are four different types of evidence for reliability, such as test–retest reliability, that are listed in Table 3.1.1.4, along with synonyms that you may see in the literature. In addition, there are many different methods to compute these different types of reliability. See Morgan, Gliner, and Harmon (3) for specifics about these approaches to assessing reliability.

Measurement Validity

Validity is concerned with establishing evidence for the use of a particular measure or instrument in a particular setting with a particular population for a specific purpose. Here we will discuss what we call measurement validity; others might use terms such as *test validity, score validity,* or just *validity*. We use the *modifier measurement* to distinguish it from internal, external, and overall research validity

and to point out that it is the measures or scores that provide evidence for validity. It is inappropriate to say that a test is "valid" or "invalid." Note also that an instrument may produce consistent data (provide evidence for reliability), but the data may not be a valid index of the intended construct.

TABLE 3.1.1.4

SIMILAR TERMS ABOUT MEASUREMENT RELIABILITY

- Alternate forms reliability ≈ equivalent forms ≈ parallel forms ≈ coefficient of equivalence
- Internal consistency reliability ≈ interitem reliability ≈ Cronbach's alpha
- Interrater reliability ≈ interobserver reliability
- Measurement reliability ≈ reliability ≈ test, instrument, or score reliability
- Test–retest reliability ≈ coefficient of stability

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right.

TABLE 3.1.1.5

EVIDENCE FOR MEASUREMENT VALIDITY

Type of Evidence	Support for Validity Depends on
Evidence based on content—all aspects of the construct are represented in appropriate proportions	Good agreement by experts about the content and that it represents the concept to be assessed
Evidence based on response processes—participants' responses match the intended construct	Evidence that participants and raters are not influenced by irrelevant factors like social desirability
Evidence based on internal structure—relationships among items on the test consistent with the conceptual framework	Meaningful factor structure consistent with the conceptual organization of the construct(s)
Evidence based on relations to other variables	
Criterion-concurrent—test and criterion are measured at the same time	The effect size of the relationship[a]
Criterion-predictive—test predicts some criterion in the future	The effect size of the relationship[a]
Convergent—based on theory, variables predicted to be related are related	The effect size of the relationship[a]
Discriminant—variables predicted not to be related are not related	The effect size of the relationship[a,b]
Validity generalization—results using the measure generalize to other settings	Supportive meta-analytic studies
Evidence based on consequences—conducting the test produces benefits for the participants	Evidence that positive consequences outweigh unexpected negative ones in terms of the outcomes of therapy, job placement, etc.

[a]The strength or level of support for validity (weak, medium, strong) could be based on Cohen's (5) effect size guidelines, with the qualifications noted in the text.
[b]Depending on the data, the appropriate strength of association statistic will vary.

In research articles, there is usually more evidence for the reliability of the instrument than for the validity of the instrument because evidence for validity is more difficult to obtain. To establish validity, one ideally needs a "gold standard" or

"criterion" related to the particular purpose of the measure. To obtain such a criterion is often not an easy matter, so other types of evidence to support the validity of a measure are necessary.

Currently, the Standards (4) categorize evidence into five *types* that support the validity of a test or measure: (a) content, (b) response processes, (c) internal structure, (d) relations to other variables, and (e) the consequences of testing (4). Note that the five types of evidence are *not* separate types of validity and that any one type of evidence is insufficient. Validation should integrate all the pertinent evidence from as many of the five types of evidence as possible. Preferably validation should include some evidence in addition to content evidence, which is probably the most common and easiest to obtain. Table 3.1.1.5 expands the description of the five types of validity evidence and what information would be used to support each type of evidence.

Many researchers still classify evidence for validity into three types: content, criterion-related, and construct. Table 3.1.1.5 shows that the two types of criterion validity (concurrent and predictive) are now under evidence based on relations. Construct validity included convergent, discriminant, and factorial evidence; the latter is under evidence based on internal structure.

Evaluation of evidence for validity is often based on correlations with other variables, but there are no well-established guidelines. Our suggestion is to use Cohen's (5) guidelines for interpreting effect sizes, which are measures of the strength of a relationship. We describe several measures of effect size and how to interpret them. Cohen suggested that generally, in the applied behavioral sciences, a correlation of $r = 0.5$ could be considered a large effect, and in this context we would consider $r = 0.5$ or greater to be strong support for measurement validity. In general, an acceptable level of support would be provided by $r \geq 0.3$, and some weak support might result from $r \geq 0.1$, assuming that such an r was statistically significant. However, for concurrent, criterion evidence, if the criterion and test being validated are two similar measures of the same concept (e.g., IQ), the correlation would be expected to be very high, perhaps 0.8 or 0.9. On the other hand, for convergent evidence, the measures should not be that highly correlated because they should be measures of different concepts. If the measures were very highly related, one might ask whether they were instead really measuring the same concept.

The strength of the evidence for the measurement of validity is extremely important for research in applied settings because without measures that have strong evidence for validity the results of the study can be misleading. Validation is an ongoing, never fully achieved, process based on integration of all the evidence from as many sources as possible.

RESEARCH APPROACHES, QUESTIONS, AND DESIGNS

Quantitative Research Approaches

Our conceptual framework includes five quantitative research approaches (randomized experimental, quasiexperimental, comparative, associational, and descriptive). This framework is helpful because it provides appropriate guidance about inferring cause and effect.

Figure 3.1.1.2 indicates that the general purpose of four of the five approaches is to explore relationships between or among variables. This is consistent with the notion that all common parametric statistics are relational, and it is consistent with the typical phrasing of research questions and hypotheses as investigating the relationship between two or more variables. Figure 3.1.1.2 also indicates the specific purpose, type of research question, and general type of statistic used in each of the five approaches.

General Purpose	Explore relationships between variables				Description (only)
General Approach	Experimental (active independent variable)		Nonexperimental (attribute independent variable)		Descriptive
Specific Approach	Randomized experimental	Quasiexperimental	Comparative	Associational	Descriptive
Specific Purpose	Determine causes	Examine causality	Compare groups	Find associations, make predictions	Summarize data
Type of Question/ Hypothesis	Difference (to compare groups)			Associational (to relate variables)	Descriptive
General Type of Statistic	Difference inferential statistics (e.g., *t* test, ANOVA)			Associational inferential statistics (e.g., correlation, multiple regression)	Descriptive statistics (e.g., histograms, means, percentages)

FIGURE 3.1.1.2. Schematic diagram showing how the general type of statistic and hypothesis or question used in a study corresponds to the purposes and the approach.

Research Approaches with an Active Independent Variable

Randomized Experimental Research Approach. This approach provides the best evidence about cause and effect. For a research approach to be called randomized experimental, two criteria must be met. First, the independent variable must be active (be a variable that is *given* to the participant, such as a treatment). Second, the researcher must randomly assign participants to groups or conditions prior to the

intervention; this is what differentiates experiments from quasiexperiments. More discussion of specific quasiexperimental and randomized designs is provided below.

Quasiexperimental Research Approach. Researchers do not agree on the definition of a quasiexperiment. Our definition is that there must be an active/manipulated independent variable, but the participants are not randomly assigned to the groups. In much applied research participants are already in groups such as clinics, and it is not possible to change those assignments and divide the participants randomly into experimental and control groups.

Nonexperimental Research Approaches

These approaches have attributed independent variables and are often called *observational studies* in the medical literature. We divide these nonexperimental approaches into comparative and associational. The distinctions between them are shown in Figure 3.1.1.2.

Comparative Research Approach. Like randomized experiments and quasiexperiments, the comparative approach, which is sometimes called *causal-comparative,* or *ex post facto,* usually has a few levels (typically two to four) or categories for the independent variable and makes comparisons between groups.

Associational Research Approach. This approach is similar to the comparative approach in that the independent variable is an attribute. In this approach, the independent variable is often continuous or has a number of ordered categories, usually five or more. We prefer to label this approach *associational* rather *correlational*, as used by some researchers, because the approach is more than, and should not be confused with, a specific statistic, the correlation coefficient.

Descriptive Research Approach

The term *descriptive research* refers to questions and studies that use only descriptive statistics, such as averages, percentages, histograms, and frequency distributions, which are not tested for statistical significance. This approach is different from the other four in that only one variable is considered at a time so that no comparisons or associations are determined. Although most research studies include some descriptive questions (at least to describe the sample), very few stop there; it is hard to find a purely descriptive study.

The approaches are based on the type of independent variable and research questions, so the whole study can and often does have more than one approach. For example, it is common for *survey research* to include both comparative and associational as well as descriptive research questions and therefore use all three approaches.

Research Questions and Hypotheses

Three Types of Basic Hypotheses or Research Questions

A *hypothesis* is a predictive statement about the relationship between two or more variables. Research questions are similar to hypotheses, but they are in question format. *Research questions* can be divided into three types: *difference questions, associational questions*, and *descriptive questions* (see Figure 3.1.1.2 again).

For difference questions, one compares groups or levels derived from the independent variable in terms of their scores on the dependent variable. This type of question typically is used with the randomized experimental, quasiexperimental, and comparative approaches. For an associational question, one associates or relates the independent and dependent variables. What we call descriptive questions are not answered with inferential statistics; they merely describe or summarize data.

As implied by Figure 3.1.1.2, it is appropriate to phrase any difference or associational research question as simply a *relationship* between the independent variable(s) and the dependent variable. However, we think that phrasing the research questions/hypotheses as a difference between groups or as a relationship between variables helps match the question to the appropriate statistical analysis. Table 3.1.1.6 shows the terms other researchers sometimes use that correspond to those for our research approaches and questions.

EXPERIMENTAL DESIGNS

We describe here specific designs for both quasiexperiments and randomized experiments. This should help the reader visualize the independent variables, levels of these variables, and whether the participants are assessed on the dependent variable more than once.

Quasiexperimental Designs

The randomized experimental and quasiexperimental approaches have an active independent variable, which has two or more values, called levels. The dependent variable is the outcome measure or criterion of the study.

In both randomized and quasiexperimental approaches, the active independent variable has at least one level that is some type of intervention given to participants in the experimental group during the study. Usually there is also a comparison or control group, which is the other level of the independent variable. There can be more than two levels or groups (e.g., two or more different interventions plus one or more comparison groups).

TABLE 3.1.1.6

SIMILAR TERMS ABOUT RESEARCH APPROACHES AND QUESTIONS

- Associational approach ≈ correlational ≈ survey ≈ descriptive
- Associational questions ≈ correlational questions
- Comparative approach ≈ causal-comparative ≈ ex post facto
- Descriptive approach ≈ exploratory research
- Difference questions ≈ group comparisons
- Nonexperimental research (comparative, associational, and descriptive approaches) ≈ some writers call all three descriptive ≈ observational research

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right.

The key difference between quasiexperiments and randomized experiments is whether the participants are assigned randomly to the groups or levels of the independent variable. In quasiexperiments random assignment of the participants is not done; thus, the groups are always considered to be nonequivalent, and there are alternative interpretations of the results that make definitive conclusions about cause and effect difficult. For example, if some children diagnosed with attention-deficit/hyperactivity disorder were treated with stimulants and others were not, later differences between the groups could be due to many factors. Families who volunteer (or agree) to have their children medicated may be different, in important ways, from those who do not. Or perhaps the more disruptive children were given stimulants. Thus, later problem behaviors (or positive outcomes) could be due to initial differences between the groups rather than the stimulant.

Poor Quasiexperimental Designs

Results from these designs (sometimes called *pre-experimental*) are hard to interpret and should not be used. These designs lack a comparison (control) group, a pretest, or both.

Better Quasiexperimental Designs

Pretest–Posttest Nonequivalent Groups Design. As with all quasiexperiments, there is no random assignment of the participants to the groups in this design. First, measurements (O_1) are taken on the groups prior to an intervention. Then one group (E) receives a new treatment (X), which the other (comparison) group (C) does not receive (NX); often the comparison group receives the usual or traditional treatment. At the end of the intervention period, both groups are measured again (O_2) to determine whether there are differences between the two groups. The design is considered to be nonequivalent because the participants are not randomly assigned (NR) to one or the other group. Even if the two groups have the same mean score on the pretest, there may be characteristics that have not been measured that may interact

with the treatment to cause differences between the two groups that are not due strictly to the intervention. The following diagram illustrates the procedures for the pretest–posttest nonequivalent groups design:

NR	E	O_1	X	O_2
NR	C	O_1	NX	O_2

Table 3.1.1.7 summarizes two issues that determine the strength (from weak to strong) of quasiexperimental designs. These designs vary, as shown, on whether the *treatments* are randomly assigned to the intact groups, such as clinics, and on the likelihood that the groups are similar in terms of attributes or characteristics of the participants. In none of the quasiexperimental designs are the *individual participants* randomly assigned to the groups, so the groups are always considered nonequivalent, but the participant characteristics may be similar if there was no bias in how the participants were assigned (got into) the groups.

Time-Series Designs. Time-series designs are different from the more traditional designs discussed above because they have multiple measurement (time) periods rather than just the pre- and postperiods. These designs often are referred to as *interrupted* time series because the treatment interrupts the baseline from posttreatment measures. The two most common types are single-group time-series designs and multiple-group time-series designs (6). Within each type, the treatment can be temporary or continuous. The logic behind any time-series design involves convincing others that a baseline (several pretests) is stable prior to an intervention so that one can conclude that the change in the dependent variable is due to the intervention and not due to other environmental events or maturation. It is common in time-series designs to have multiple measures before and after the intervention, but there must be multiple (at least three) pretests to establish a baseline. One of the hallmarks of time-series designs is the visual display of the data, which are often quite convincing. However, these visual displays also can be misleading due to the lack of independence of the data points, and therefore always must be statistically analyzed.

TABLE 3.1.1.7

ISSUES THAT DETERMINE THE STRENGTH OF QUASIEXPERIMENTAL DESIGNS

Strength of Design	Random Assignment of Treatments to Intact Groups	Participant Characteristics Likely to Be Similar
Poor (or pre)	No	No, because no comparison group or no pretest
Weak	No	Not likely, because participants decide which group to join (self-assign to groups)
Moderate	No	Maybe, because participants did not self-assign to

Strong	Yes	Maybe, because participants did not self-assign to groups and no known assignment bias

Randomized Experimental Designs

In randomized designs the participants are randomly assigned to the experimental and control groups. Random assignment of participants to groups should eliminate bias on all characteristics before the independent variable is introduced. This elimination of bias is one necessary condition for the results to provide convincing evidence that the independent variable caused differences between the groups on the dependent variable. For cause to be demonstrated, other biases in environmental and experience variables occurring during the study also must be eliminated.

Three types of randomized experimental designs are discussed. For each we describe and diagram the design and present some of the advantages and disadvantages. The diagrams and discussion are limited to two groups, but more than two groups may be used with any of these designs. The experimental group receives the intervention, and the “control” group(s) receives the standard (traditional) treatment, a placebo, and/or another (comparison) treatment. For ethical reasons, it is unusual and not desirable for the control group to receive no treatment at all, but it is difficult to decide which type of control group is appropriate. Here we call all such treatment options the *control group*.

Posttest-Only Control Group Design

The posttest-only control group design can be shown as follows:

R	E:	X	O
R	C:	NX	O

The sequential operations of the design are to randomly (R) assign participants to either an experimental (E) or control (C) group. Then the experimental group receives the intended intervention (X) and the control group does not receive it (NX). At the end of the intervention period, both groups are measured (O), using some form of instrumentation related to the study (dependent variable).

The key point for the posttest-only control group design is the random assignment of participants to groups. If participants are assigned randomly to one or the other group, the two groups should not be biased on *any* variable prior to the intervention. Therefore, if there are differences on the dependent measure following the intervention, it can be assumed that the differences are due to the intervention and not due to differences in participant characteristics.

Pretest–Posttest Control Group Design

The pretest–posttest control group design can be shown as follows:

R	E:	O_1	X	O_2
R	C:	O_1	NX	O_2

Reasons for using this design compared with the posttest-only control group design are to check for equivalence of groups before the intervention and to describe the population from which both groups are drawn. Another advantage of this design is that posttest scores could be adjusted statistically through analysis of covariance based on pretest score differences between the treatment and control groups. On the other hand, a problem could be created if a pretest is used. The pretest could bias the participants as to what to expect in the study, and practice on the pretest could influence the posttest (there could be carryover effects). Also, if the dependent variable is invasive (spinal tap), one would not want to use it as a pretest. Random assignment does mean that the groups will not differ substantially on the average, but this assurance is adequate only if the sample is large. In small-sample clinical research, it is not uncommon to find some large differences in important characteristics even when the participants were randomly assigned to groups.

Within-Subjects Randomized Experimental (or Crossover) Design

In the simplest case, this design has two levels and can be shown as follows:

		Condition 1	Test	Condition 2	Test
R	Order 1	X	O_1	NX	O_2
R	Order 2	NX	O_1	X	O_2

The participants are randomly assigned to order 1, which receives the experimental condition first and then the control condition, or to order 2, which receives the control condition and then the experimental. This type of design is frequently used in studies in which participants are asked to evaluate diets, exercise, and similar events assumed, from previous research, not to have carryover effects. The strength of this design is that participants act as their own control, which reduces error variance. This design can have problems if there are carryover effects from the experimental condition. Furthermore, one must be extremely cautious with this design when comparing a new treatment with a traditional treatment. The problem, often referred to as *asymmetrical transfer effects,* occurs when the impact of one order (perhaps the traditional treatment before the new treatment) is greater than the impact of the other order (new treatment before the traditional treatment).

Many variants of the above quasiexperimental and experimental designs are discussed in Shadish, Cook, and Campbell (7).

GENERAL DESIGN CLASSIFICATIONS

GENERAL DESIGN CLASSIFICATIONS

General design classifications are important for determining appropriate statistical methods to be used in data analysis. Within the randomized experimental, quasiexperimental, and comparative approaches, all designs must fit into one of three categories or labels (between, within, or mixed). These design classifications do not apply to the associational or descriptive approaches.

Between-Groups Designs

Between-groups designs are defined as designs in which each participant in the research study is in one and only one condition or group. For example, in a study investigating the effects of medication on the number of symptoms in hyperactive children, there might be two groups (or conditions or levels) of the independent variable: the current medication and a new medication. In a between-groups design, each participant receives only one of the two conditions or levels: either the current medication or the new one.

Within-Subjects or Repeated-Measures Designs

Within-subjects designs, the second type of general design classification, are conceptually the opposite of between-groups designs. In these designs, each participant in the research receives or experiences all of the conditions or levels of the independent variable. If we use the hyperactive children example just given, there still would be two conditions or levels to the independent variable. In a within-subjects design, each participant would be given first one medication, then the second medication and would be measured for the number of symptoms on both conditions. Because each participant is assessed more than once (for each condition), these designs are also referred to as repeated-measures designs.

Within-subjects designs have appeal due to the reduction in participants needed and to reduction in error variance because each participant is in his or her own control. However, often these designs are less appropriate than between-groups designs because of the possibility of *carryover effects*. If the purpose of the study is to investigate conditions that may result in a long-term or permanent change, such as learning, it is not possible for a participant to be in one condition and then "unlearn" that condition to be in the same previous state to start the next condition. Within-subjects designs may be appropriate if the effects of order of presentation are negligible, as when participants are asked to evaluate several topics or when a medication effect would not be long lasting.

Matching is a second situation where a design is judged to be within subjects. When pairs of subjects in a comparison group and an experimental group are matched

on key characteristics, the design is treated statistically as within subjects.

TABLE 3.1.1.8

SIMILAR TERMS ABOUT RESEARCH DESIGNS

- Between groups ≈ independent samples
- Comparison group ≈ control group ≈ placebo group
- Factorial design ≈ two or more independent variables ≈ complex design
- Poor quasiexperimental designs ≈ pre-experiments
- Random assignment to groups ≈ randomized design
- Randomized experiment ≈ true experiment ≈ randomized clinical trial ≈ randomized control trials ≈ RCT
- Single factor design ≈ one independent variable ≈ basic design
- Within subjects ≈ repeated measures ≈ related samples ≈ paired samples ≈ matched groups ≈ correlated samples ≈ within groups ≈ dependent samples

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right.

Mixed Designs

A mixed design has at least one between-groups independent variable and at least one within-subjects independent variable; thus there are a minimum of two independent variables. A between-groups independent variable is any independent variable that sets up between-groups conditions. A within-subjects independent variable is any independent variable that sets up within-subjects conditions.

Change Over Time (or Trials) as an Independent Variable

In within-subjects designs, there can be a third type (neither active nor attribute) of independent variable, called change over time or trials. This third type of independent variable is extremely important in randomized experimental and quasiexperimental designs because pretest and posttest are two levels of this type of independent variable. Longitudinal studies, in which the same participants are assessed at several time periods or ages, are another important case in which change over time is the independent variable.

Table 3.1.1.8 provides examples of terms for research designs sometimes used by other researchers that have meanings similar to ours.

DIMENSIONS OF RESEARCH VALIDITY

Research validity refers to the merit of the design of a whole study, as distinguished from validity of the measurement of a variable. Based on the work of Cook and Campbell (6), we (3) divide research validity into four key components:

1. *Measurement reliability and statistics.* We discussed the reliability above and

will discuss the appropriate use and interpretation of statistics below.

2. *Internal validity* to be discussed below.
3. *Overall measurement validity of the constructs* which was discussed briefly above.
4. *External validity* which is how well the results of the study generalize to other populations, settings, treatments, and measures.

The next section describes briefly the issue of cause and effect, which is key to understanding internal validity.

Inferring Cause

A major goal of scientific research is to be able to identify a causal relationship between variables. Researchers note that even if they cannot identify all the causes or the most important causal factor of an outcome, they can identify a variable as one (or a partial) cause, under certain circumstances. Three criteria that must occur to infer a causal relationship: (a) the independent variable must precede in time the dependent variable; (b) there must be a relationship between the independent variable and the dependent variable (in the behavioral sciences this is usually determined statistically); and (c) there must be no plausible third (extraneous) variable that also could account for a relationship between the independent and dependent variables.

Four of the five specific research approaches (except the descriptive) attempt to satisfy the three prerequisites. All four can, but do not always, meet the first two criteria, the independent variable preceding the dependent variable and establishing a relationship between variables. The randomized experimental and, to a much lesser extent, the quasiexperimental approaches can be successful in meeting the third condition, elimination of extraneous variables. The comparative and associational approaches are not well suited to establishing causes, but things can be done to control for some extraneous variables. Although the comparative and associational approaches are limited in what can be said about causation, they can lead to strong conclusions about the differences between groups and about associations between variables, respectively. For example, strong associations (correlations) between variables can generate equations where knowing a score on one variable allows one to predict, with some degree of accuracy, the score on the other variable (linear regression). The descriptive approach, as we define it, does not attempt to identify causal relationships or, in fact, any relationships. It focuses on describing variables.

Internal Validity

Cook and Campbell (6) defined internal validity as “the approximate validity with which we can infer that a relationship is causal.” Internal validity depends on the strength or soundness of the design and influences whether one can conclude that the

independent variable or intervention caused the dependent variable to change. Although internal validity is often discussed only with respect to randomized and quasiexperiments, we believe the concept also applies to research with attribute independent variables (and nonexperimental studies).

We group the Shadish et al. (7) threats to internal validity into two main types: *equivalence of the intervention and control groups on participant characteristics prior to and during the intervention* and *control of extraneous experiences and environmental variables.*

Equivalence of Groups on Participant Characteristics

In research that compares differences among groups, a key question is whether the *groups* that are compared are *equivalent in all* respects prior to the introduction of the independent variable or variables. Using the randomized experimental approach, equivalence is approximately achieved through random assignment of participants to groups, especially if the sample size in each group is large. Random assignment of participants to the groups, which is characteristic of randomized experiments but not quasiexperiments, is the best way to ensure equivalent, or at least unbiased, groups. However, in quasiexperimental, comparative, or associational research, random assignment of participants to groups has not been or cannot be done.

TABLE 3.1.1.9

THREATS TO INTERNAL VALIDITY

Shadish, Cook, and Campbell (7)	Morgan, Gliner, and Harmon (3)
	Equivalence of Groups
Regression	Use of extreme groups
Attrition/mortality	Participant dropouts/attrition during the study
Selection	Bias in assignment to groups
	Control of Extraneous Variables
Maturation	Changes due to time or growth/development
History	Extraneous events
Testing	Repeated testing, carryover effects
Instrumentation	Measurement inconsistency
Additive and interactive threats	Combinations of two or more threats
Ambiguous temporal precedence	Did the independent variable occur before the dependent variable?

Control of Extraneous Experiences and Environment Variables

We have grouped several other “threats” to internal validity under a category that deals with the effects of extraneous (variables other than the independent variables) experiences or environmental conditions during the study. Thus, we have called this

internal validity dimension *control of extraneous experiences and environment variables*. Many of these threats occur because participants gain information about the purpose of the study while the study is taking place. An important aspect of this dimension has to do with whether extraneous variables or events *affect one group more* than the other. For example, if participants learn that they are in a control group, they may give up or not try as hard, exaggerating differences between the intervention and control groups; or the opposite may occur and those in the control group overcompensate, eliminating differences between the two groups.

Control of extraneous experiences and the environment depends on the specific study, but it is generally better for randomized experiments and for studies done in controlled environments such as laboratories.

Threats to Internal Validity

Table 3.1.1.9 provides a current list of threats to interval validity as described by Shadish et al. (7). Some of the names for the various threats are confusing, but the concepts are important. We have added a column for our suggested names.

Sampling and Population External Validity

Sampling is the process of selecting part of a population of potential participants with the intent of generalizing from the smaller group, called the *sample*, to the *population*. If we are to make valid inferences about the population, we must select the sample so that it is *representative* of the population. With a few notable exceptions, modern survey techniques have proven to be quite accurate in selecting representative samples and making inferences about the population.

Steps in Selecting a Sample and Generalizing Results

There are many ways to select a sample from a population. The goal is to have an *actual sample* in which each participant represents a known fraction of the *theoretical* or *target population* so that characteristics of the population can be recreated from the sample. Obtaining a *representative sample* is not easy because things can go wrong at three stages of the research process. Figure 3.1.1.3 shows the key sampling concepts and the three steps (shown with arrows).

Target or theoretical population
(e.g., all ADHD children in USA)

(Step 1)

Accessible population or
sampling Frame

(500 ADHD children from 10
university clinics)

Sampling Design or Selection
(step 2)

Selected sample
$N = 100$

(Step 3)

Actual sample
$N = 75$

Assignment to Groups
(Step 4)

Group 1
$N = 25$

Group 2
$N = 25$

Group 3
$N = 25$

External Population Validity
depends on sampling design

Highest = If you select the whole population and it is the accessible population of interest

High = Probability sampling, e.g., simple random

Lower = Nonprobability sampling, e.g., convenience

Internal Validity
depends, in part, on how participants get into groups

High = Random assignment

Lower = groups already intact or groups based on attributes

Lowest = Self-selection based on knowledge of the treatment

FIGURE 3.1.1.3. Schematic diagram of the sampling process and the distinction between random sampling and random assignment.

Types of Sampling

There are two major types of sampling designs that are used in obtaining the selected sample: probability (often considered unbiased sampling) and nonprobability (often considered biased sampling).

Probability Sampling. In probability sampling, every participant has a known, nonzero chance of being selected. The participants or elements of the population are usually people, but could be groups, animals, or events. With probability samples, researchers are able to make an estimate of the extent to which results based on the sample are likely to differ from what would have been found by studying the entire population. There are several types of probability sampling. The most basic is the

simple random sample, which occurs when all participants have an equal and independent chance of being included in the sample. This technique can be implemented using a random number table to select participants from a list, the sampling frame, of the accessible population.

If some important characteristics of the accessible population such as gender or race are known ahead of time, one can reduce the sampling variation and increase the likelihood that the sample will be representative of the population by using *stratified random sampling*.

Nonprobability Sampling. These samples are ones in which the probability of being selected is unknown. Time and cost constraints lead many researchers to use nonprobability samples. The most common type of nonprobability sample is called a *convenience sample*. A sample is considered a convenience sample if the researcher selected either the accessible population or some participants from the accessible population based on convenience. An extended discussion of the types of sampling and the advantages and disadvantages of each can be found in Fowler (8).

How Many Participants?

The question, "How many participants are needed for this study?" is asked often. One part of the answer depends on whom you ask and their discipline (9). The size of the sample should be large enough so one does not fail to detect important findings, but a large sample will not necessarily help one distinguish the merely statistically significant from societally important findings. *Statistical power analysis* can help one compute the sample size needed to find a statistically significant result given certain assumptions (5).

Sampling and the Internal and External Validity of a Study

We have discussed the internal and external validity of a study and noted that external validity is influenced by the representativeness of the sample. Figure 3.1.1.3 also shows how the two uses of the word *random* have quite different meanings and different effects on internal and external validity. A probability sampling method such as *random selection* (Step 2) of who is asked to participate in the study is important for high external validity. On the other hand, *random assignment* or placement into groups of persons who agree to participate (Step 4), is important for high internal validity.

TABLE 3.1.1.10

SIMILAR TERMS ABOUT SAMPLING

- Accessible population ≈ sampling frame
- Actual sample ≈ sample ≈ final sample
- Convenience sampling ≈ nonprobability sampling ≈ biased sampling

- Random selection ≈ random sampling ≈ probability sampling
- Response rate ≈ return rate ≈ percentage of selected sample participating
- Selected sample ≈ participants sampled
- Theoretical population ≈ target population ≈ population of interest

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right.

Table 3.1.1.10 provides alternate terms used by researchers for various aspects of the sampling process.

INFERENTIAL STATISTICS AND THEIR INTERPRETATION

Introduction to Inferential Statistics and Hypothesis Testing

There are two general approaches to performing quantitative research (10). One, the hypothesis testing approach, often referred to as null hypothesis significance testing (NHST), is the more traditional approach, and focuses on the outcomes of single studies. A second, more recent approach, referred to as the evidence based approach, focuses on conducting multiple studies and the reliability of a research finding. The two approaches are not independent of each other, and often NHST is included in the second approach but not always.

When performing research, rarely are we able to work with an entire population of individuals. Instead, we usually conduct the study on a sample of individuals from a population. It is hoped that if the sample is representative we can infer that the results from our sample apply to the population of interest. Inferential statistics involve making inferences from sample statistics, such as the sample mean and the sample standard deviation, to population parameters such as the population mean and the population standard deviation.

The Hypothesis Testing Approach

The goal of null hypothesis significance testing (NHST) is to reject the null hypothesis in favor of an alternative hypothesis. The *null hypothesis* states that the mean of the population of those who receive the intervention is equal to the mean of the population of those who do not. In other words, the intervention is not successful. An alternative hypothesis (our hypothesis of interest) states that the mean of the population of those who receive the intervention will be greater than the mean of the population of those who do not. If the null hypothesis is false, or rejected, the intervention is considered to be successful. Note that the null hypothesis was stated as a “no difference” null hypothesis, that is, that there is no difference between the population means of the treatment and control groups. However, especially in practical applications, the null hypothesis could be stated, but is not often, as some

specific functionally important difference between the means of the two populations. In that case, to reject the null hypothesis, the treatment group would have to exceed the control group by an amount necessary to make a *functional* difference. This is referred to as a *nonnil null hypothesis*.

The hypothesis testing process can be summarized as a series of steps that the researcher takes to conduct the study. From the accessible population, a sample is selected. Participants in this sample are then assigned, randomly under the best circumstances, to one of two groups, an intervention group and a comparison group. (More than two groups could be used, such as two treatment groups and a comparison group.) Next, the participants in the intervention group undergo the new treatment and the participants in the comparison group receive the standard or traditional treatment. At the end of the treatment period, both groups are measured on the dependent variable and a comparison is made, usually between the means of the two groups.

How much of a difference between the two means is needed before one can conclude that there is a statistically significant difference? Inferential statistics provide an outcome (a statistic) that helps make the decision about how much of a difference is needed. However, even after performing inferential statistics, one is still making a decision with some degree of uncertainty.

An outcome that is highly unlikely (i.e., one that results in a low probability value) if the null hypothesis were true leads one to reject the null hypothesis. Most researchers set this probability value (alpha) as five times in 100, or 0.05. An outcome that is more likely (>0.05) will result in a failure to reject the null hypothesis.

Type I and Type II Errors

Although inferential statistics help one make a decision (e.g., reject or not reject the null hypothesis), there is still a possibility that the decision made may be incorrect because the decision is based on the *probability* of a given outcome. Figure 3.1.1.4 shows that four outcomes are possible; two of the outcomes are correct decisions and two are errors. The correct outcomes are (a) to not reject the null hypothesis when it is true (there is, in fact, no difference) and (b) to reject the null hypothesis when it is false (a correct decision that there is a difference). The error of commission is (c) to reject the null hypothesis when, in fact, it is true—type I error (saying that there is a difference when there really was no difference). The error of omission is (d) to not reject the null hypothesis when it is false—type II error (saying that there was no difference when there really was a difference).

Statistical Power

Statistical power is the probability of a correct decision to *reject the null hypothesis*

when it is false. Conventionally, the desired statistical power of a study is 0.80. Because statistical power is inversely related to a type II error, that error would be 0.20 if power is 0.80.

Although there are numerous methods to increase statistical power, the most common is to increase the size of the sample. In order to determine how many participants to include in a study, one must know the significance level (usually established at 0.05), type of hypothesis (directional or nondirectional), desired power (0.8 if possible), and an estimate of the effect size (the strength of the relationship between the independent variable and the dependent variable, often stated in standard deviation units). Effect size information comes from a review of the literature on the topic. Most current research syntheses contain a meta-analysis that results in an effect size estimate.

Researcher's decision based on NHST of the *sample* data

Reject the null hypothesis (H_0)

Do not reject the null hypothesis (H_0)

Then there is a **type I error** (α, alpha)

If the null hypothesis is really *true* (no difference in the population)

Then there is a **correct decision** ($1-\alpha$)

Then there is a **correct decision** ($1-\beta$ or Power)

If the null hypothesis is really *false* (there is a difference in the population)

Then there is a **type II error** (β, beta)

FIGURE 3.1.1.4. Flow chart showing the four possible outcomes (two correct and two errors, type I and type II) that could result from a decision to reject or not reject a null hypothesis.

Once the information (significance level, type of hypothesis, amount of power, and effect size) has been obtained, a power table or computer program can be used to determine the needed number of participants. Although increasing the number of participants in a study is a good way to increase statistical power, often this option is not possible. In program evaluation, frequently the number of participants is fixed,

often below that desired for adequate power. There are other methods to increase power, such as using homogeneous groups, making sure the measure has strong evidence for reliability, and sometimes choosing a within-subjects design to reduce variability. Lipsey (11) and Cohen (5) provided valuable information on this topic.

More Points about Hypothesis Testing

Three more points about inferential statistics and hypothesis testing need to be considered. First, when the null hypothesis is not rejected, it is never actually accepted. There could be many reasons why the study did not result in a rejection of the null hypothesis. Perhaps another more powerful or better designed study might result in a rejection of the null hypothesis.

Second, testing the null hypothesis is a key part of all types of inferential statistical procedures used with all of our research approaches except the descriptive approach.

Last, in order to provide a fair test of the null hypothesis, there must be adequate statistical power. A power analysis should be planned prior to the study.

Practical Significance Versus Statistical Significance

A common misinterpretation is to assume that statistically significant results are practically or clinically important, but statistical significance is not the same as practical significance or importance. With large samples, statistical significance can be obtained even when the differences or associations are very small/weak. Thus, in addition to statistical significance, it is important to examine confidence intervals and/or the effect size.

An Evidence-Based Approach to Quantitative Research

While there have been numerous criticisms of NHST (10), perhaps the most important is the limited focus on a single study and its dichotomous outcome of whether the result was statistically significant or not. Furthermore, when we dichotomize statistical significance, we become removed from the actual data of our study. Underlying the evidence-based approach is the knowledge that a single study is not sufficient to use as evidence to substantiate a hypothesis or theory. The evidence-based approach relies less on statistical significance and more on confidence intervals and effect sizes.

Confidence Intervals

Confidence intervals (CI) use the same information that is needed to perform NHST. In the above section on NHST, we gave an example of comparing an intervention

group who received therapy with a group that did not receive therapy. We stated that the mean of the population of those who receive the intervention will be greater than the mean of the population of those who do not receive the intervention. Using NHST, our outcome is expressed as a difference between sample means, and a statement of significance at a preset alpha level. With confidence intervals, our outcome is expressed as an interval around the sample mean with a lower and upper boundary and a level of confidence (usually 95%). Confidence intervals give an estimate of an interval that includes the actual population mean (or in many cases, an estimate of the difference between the intervention and control means). Unfortunately, the confidence interval derived from a single study does not necessarily include the population mean. Typically speaking, if 95% confidence intervals were developed on 100 studies, using the same sample size, independent and dependent variables, the confidence intervals in 95 of the studies would include the population mean and five would not. That is why confidence intervals are become more important for *multiple studies*.

If one increases the CI from 95% to 99%, and confidence that the true population mean (or difference between means) is in the interval also increases. However, other things being equal, the range (breadth) of the confidence interval also increases.

Effect Size

While confidence intervals always should be reported, they also have limitations. One of the problems is that the dependent variable from study to study must be the same to compare the different intervals. Unfortunately, exact replications of previous work are relatively rare because they are not rewarded by academic institutions. Therefore, replications of previous work are likely to involve some alteration of the independent variable, the dependent variable, or both. To solve this problem, researchers have added a second strategy to the evidence-based approach: effect size. As will be pointed out later in this chapter, numerous studies can be synthesized using effect sizes to provide an overall estimate of the effect on the independent variable (intervention) on the dependent variable (outcome).

A statistically significant outcome does not give information about the strength or size of the outcome or the effect. Effect size is the strength of the relationship between the independent variable and the dependent variable and/or the magnitude of the difference between levels of the independent variable with respect to the dependent variable. Statisticians have proposed effect size measures that fall mainly into three types or families: the r family, the d family, and measures of risk potency. We discuss these effect sizes and clinical significance in more detail below.

Steps in Interpreting Inferential Statistics

To fully interpret the results of an inferential statistic, the author should consider four

issues.

First, decide whether to reject the null hypothesis, as discussed earlier.

Second, the direction of the effect should be stated. Difference inferential statistics compare groups, so which group performed better should be noted. For associational inferential statistics (e.g., correlation), the sign is very important, so whether the association or relationship is positive or negative should be clear.

Third, the effect size should be included in the description of the results or, at the least, the information to compute it should be presented. The interpretation of the effect size is subjective.

Fourth, the researcher or the consumer of the research (clinician and patient/client) should make a judgment about whether the result has practical or clinical significance or importance. To do so the effect size, the costs of implementing change, and the probability and severity of any side effects or unintended consequences need to be taken into account.

Examples of the Use and Interpretation of Statistics

In Figure 3.1.1.2 we divided research questions into difference questions and associational questions. *Difference questions* compare groups and utilize the statistics, which we call *difference inferential statistics* (e.g., *t* test and analysis of variance). *Associational questions* examine the association or relationship between two or more variables. They utilize *associational inferential statistics* (correlation and regression). Figure 3.1.1.5 is a decision tree that shows how researchers might make a decision about what type of inferential statistic to use. A clinician/reader might work backward from a reported statistic to understand a rationale for the choice of a statistic.

The following examples are from articles published in the *Journal of the American Academy of Child and Adolescent Psychiatry.* Readers can find the original study in the reference list or they can see an expanded version of our description of the study and how the cited statistic was interpreted in Morgan et al. (3).

Basic (Two Variable) Difference Questions and Statistics. For the *independent samples t test* and *one-way ANOVA,* the article we selected was by Herpertz et al. (12), who compared three groups of boys on psychophysiological and other measures (e.g., IQ). They had three levels of the independent variable, (ADHD, ADHD + CD, and a comparison group without ADHD), a between- or independent-groups design (unrelated children in each group), and a normally distributed dependent variable (IQ), so an appropriate statistic was one-way ANOVA to compare the three levels or groups. A nonparametric statistic could have been used to compare the three groups of boys if the ANOVA assumptions had been markedly violated. If Herpertz et al. had just compared two of the groups (e.g., ADHD and ADHD + CD) they could have

used an independent samples *t* test.

To illustrate the *paired samples t test* and *repeated-measures ANOVA,* we chose an article by Compton et al. (13), who assessed the benefits of sertraline in adolescents with social anxiety disorder in an open 8-week trial. They applied the paired *t* test to assess whether there was a change from the baseline to the end of the trial on the behavior avoidance test. They used repeated-measures ANOVA to determine whether there was clinical improvement at 2, 4, 6, and 8 weeks compared to the baseline. These statistics were used because there was one group of adolescents assessed repeatedly (within-subjects design).

Basic (Two Variable) Associational Questions and Statistics. Dierker et al. (14) chose *Pearson correlations* to study the association or relationship between depression (CES-D scale) and anxiety (RCMAS). Note that both variables had many levels ranging from low to high, and these variables were at least approximately normally distributed.

A study by Wolfe et al. (15) was selected to illustrate the applicability of *chi-square*. They examined the relationship between family intactness (yes or no) and maltreatment classification (maltreated in the past or not). Note that both variables were dichotomous and produce a 2 × 2 contingency table. We will discuss risk potency effect size measures such as odds ratio (OR) and risk ratio (RR), which are commonly used to help researchers and clinicians interpret data from 2 × 2 tables.

Complex (Three or more Variable) Questions and Statistics. When there are three or more variables, we call the statistics complex rather than multivariate, because there is not unanimity about the definition of multivariate, and several such complex statistics (factorial ANOVA) are not usually classified as multivariate. It is possible to break down a complex research problem or question into a series of basic (bivariate) questions and analyses as above. However, there are advantages to combining several bivariate questions into one complex analysis: Additional information is provided and a more accurate overall picture is obtained.

What type of research question?
Are there many (5+) **ordered** levels of the independent variable?

NO → **Difference question** (compares groups)

Is there more than one independent variable?

No → **Basic single factor difference statistics**

Between groups: e.g., *t* tests, single factor ANOVA, Mann-Whitney *U*
OR
Within subjects: e.g., paired *t*, repeated measures ANOVA

Yes → **Multifactor difference statistics**

e.g., between, within, or mixed factorial ANOVAs

YES → **Associational question** (Relates variables)

Is there more than one independent variable?

No → **Bivariate associational statistics**

e.g., Pearson correlation, Spearman rho

Yes → **Multivariate associational statistics**

e.g., multiple regression, logistic regression

FIGURE 3.1.1.5. A decision tree for the selection of an appropriate inferential statistic.

Conners et al. (16) selected *factorial ANOVA* to study the effects of four types of treatment and six treatment sites (a 4 × 6 factorial design) on a composite change or improvement scores in children with ADHD. Note that there are two between-groups independent variables (treatment type and site) and one dependent variable (improvement in ADHD symptoms).

Multiple regression was chosen by Logan and King (17) to study the extent of parents' ability to identify signs of depression in their adolescents (the dependent variable). They examined whether a combination of several independent variables would predict the degree to which parents could identify depression. Some of those independent variables were continuous and some were dichotomous.

Mick et al. (18) selected *logistic regression* to study whether children who had been diagnosed with ADHD or not (the dependent variable) seemed to be influenced by prenatal exposure to smoking, alcohol, and/or drug use. These and several of the "control" independent variables were dichotomous (parent smoked or did not smoke).

When there is a design similar to that appropriate for a *t* test or ANOVA but there are *two or more* normally distributed dependent variables that are moderately interrelated, it is desirable to consider treating the variables simultaneously with a *multivariate analysis of variance* (MANOVA). Marmorstein and Iacono (19) chose MANOVA to study differences between depression (yes or no) and conduct disorder (yes or no) on a linear combination of several dependent variables (grade point average, number of school suspensions, number of substance abuse symptoms) considered together.

The General Linear Model

Exploring the *relationship between variables can be addressed in two ways* as shown in Figure 3.1.1.6. Researchers choose to use either difference or associational statistics, but statisticians point out that the distinction between difference and associational statistics is artificial, as both serve the purpose of exploring and describing relationships (top box) and both are subsumed by the *general linear model* (middle box); that is, all common parametric statistics are relational. Thus, all of the methods used to analyze one continuous dependent variable and one or more independent variables, either continuous or categorical, are mathematically equivalent.

The bottom part of Figure 3.1.1.6 indicates that a *t* test or one-way ANOVA with a nominal or dichotomous independent variable is analogous to eta, which is a correlation coefficient for a nominal independent variable and a continuous dependent variable. Likewise, a one-way ANOVA with a continuous independent variable is analogous to bivariate regression. Thus, if there is a continuous, normally distributed dependent/outcome variable and there are five or more levels of a normally distributed independent variable, it would be appropriate to analyze it with either regression or a one-way ANOVA. Finally, as shown in the lowest boxes in Figure 3.1.1.6, factorial ANOVA and multiple regression are analogous mathematically.

Although our distinction between difference and associational parametric statistics is a simplification, we think it is useful educationally. Table 3.1.1.11 provides a list of sometimes confusing statistical terms and alternative names for them. The appendix provides a list of some research terms which are partially similar (or overlapping), but need to be distinguished.

SUMMARIZING STATISTICAL OUTCOMES

Meta-analysis: Formulation and Interpretation

Meta-analysis is a research synthesis of a set of studies that uses a quantitative measure, effect size, to indicate the strength of relationship between the treatment or other independent variable and the dependent variables. Not all research syntheses are meta-analyses. Often, the purpose of a research synthesis is to provide a description of a subject area, illustrating the studies that have been undertaken. In other cases, the studies are too varied in nature to provide a meaningful effect size index. The focus of this section, however, is on research syntheses that result in a meta-analysis. (For a more detailed discussion see Lipsey and Wilson [20].)

TABLE 3.1.1.11

SIMILAR TERMS ABOUT STATISTICS

- Alternative hypothesis ≈ research hypothesis ≈ H_1
- ANOVA ≈ *F* ≈ analysis of variance ≈ overall or omnibus *F*
- Associate variables ≈ relate ≈ predict → correlation or regression
- AUC ≈ probability of a superior (better) outcome
- Basic inferential statistics ≈ univariate statistics (one IV and one DV) ≈ also called bivariate statistics
- Compare groups ≈ test differences → *t* or ANOVA
- Complex inferential statistics ≈ multifactor statistics (more than one IV) ≈ multivariate statistics (usually more than one DV)
- Data mining ≈ fishing ≈ snooping ≈ multiple significance tests (without clear hypotheses)
- Multiple regression ≈ multiple linear regression
- Null hypothesis ≈ Ho
- Post hoc test ≈ follow-up tests ≈ multiple comparisons
- Repeated-measures ANOVA ≈ within-subject ANOVA
- Risk difference ≈ absolute risk reduction
- Significance level ≈ alpha level ≈ α
- Significance test ≈ null hypothesis significance test ≈ NHST
- Single-factor ANOVA ≈ one-way ANOVA

Note: The term we use most often is listed on the left. Similar terms (indicated by ≈) used by other researchers and/or us are listed to the right, and → means "leads to."

One advantage of performing a meta-analysis includes the computation of a summary statistic for a large number of studies. This summary statistic provides an overall estimate of the strength of relationship between independent and dependent variables. A second advantage of meta-analysis is that it provides evidence of the reliability of a research finding. Researchers have more confidence in the findings of multiple studies than in the results of a single study. A third advantage is that it takes into account studies that failed to find statistical significance and may not have been published, perhaps because of a lack of statistical power (reduced sample size). A fourth advantage of meta-analysis is increased external validity. Many studies, strong in internal validity (design characteristics), do not use a representative sample of subjects. This limits the generalization of results. However, including many studies increases the variation of the sample and strengthens external validity.

Although there are many advantages to meta-analysis, there also has been considerable criticism. The most frequent criticism of meta-analysis is that it may combine "apples and oranges." Synthesizing studies that might differ on both independent and dependent variables brings into question the usefulness of the end product. Furthermore, many studies have similar independent and dependent variables, but differ in the strength of design. Should these studies be combined? Another criticism concerns small sample size. Introducing a large proportion of studies with inadequate statistical power into a meta-analysis could introduce bias into the overall effect size. Last, even though the statistics used in meta-analysis are quite sophisticated, the end product will never be better than the individual studies that make up the meta-analysis.

Criteria for Review

Although much of the focus of meta-analysis is on statistical procedures, perhaps the most important part of a meta-analysis is the planning of inclusion and exclusion criteria for selecting a study into the meta-analysis. These inclusion and exclusion criteria are often related to internal validity and external validity. Most researchers feel that meta-analyses composed of randomized control trials (RCTs) represent the gold standard for clinical research.

Statistical Computations for Individual Studies

Type of Effect Size. There are numerous types of effect size indices. Briefly, the *d* effect size indicates the strength of a relationship between an independent and dependent variable in standard deviation units. The most common effect size indices used in meta-analyses are *d*, *r*, and OR, although RR and number needed to treat (NNT) also have been used.

Number of Effect Sizes. Each study in the meta-analysis should yield at least one effect size. It is not uncommon, however, to observe studies that compare a treatment group with a control group on many measures. An effect size could be computed for each measure of the study. However, when studies have more than one measure, the measures are usually related or correlated. Thus, computing more than one effect size yields redundant information and gives too much weight to that particular study. Therefore, the researcher should select one representative measure from the study or use a statistical method to determine a representative measure.

Weights. For the most part, each study included in the meta-analysis is based on a different sample size. Studies with larger sample sizes are likely to be better estimates than studies with small sample sizes. Therefore, in order to take sample size into consideration when the effect sizes are averaged, a weight is computed for each effect size. Effect sizes also can be weighted by other important indices, such as

quality of the study.

Computation of Combined Effect Size for Studies and Related Statistics

When all studies that meet the criteria for inclusion in the meta-analysis have been coded and effect size data entered, a *combined effect size* can be computed. Frequently there is an effect size computed for each construct. In addition to a mean effect size index computed for each construct, a confidence interval, usually 95%, also is obtained. Analyses also are performed to test for statistical significance, computing a z statistic, and to test for homogeneity, computing a Q statistic. If Q is statistically significant, the null hypothesis of homogeneity is rejected and the researcher assumes a heterogeneous distribution.

The most common follow-up procedure when a test for homogeneity of effect size distribution is statistically significant is to attempt to identify the variability that is contributing to the heterogeneity. Most often, the researcher has in mind, prior to the meta-analysis, certain hypotheses about which variables might contribute to variability in the mean effect size. These variables (such as strength of research design, sample subgroups, gender) are usually referred to as *moderator* variables.

Moderator variables are variables that interact with the independent variable to *cause* the change in the dependent variable. For example, gender might be a moderator variable that interacts with treatment such that there is only a success in women and not men. Moderator variables are often confused with *mediator* variables. Mediator variables are intervening variables between the independent and dependent variables that help explain the change in the dependent variable. For example, a meta-analysis might find class size (independent variable) is inversely related to student achievement (dependent variable). The mediator variable might be teacher attention, which intervenes between the independent and dependent variables.

Meta-analysis is a valuable tool for both the researcher and the clinician. Summarizing the results of many studies as an effect size index provides important strength of relationship information. Caution always should be used concerning the types of studies that went into the meta-analysis; especially, one should be aware of design issues.

Effect Sizes and Clinical Significance

Behavioral scientists are interested in answering three basic questions when examining the relationships between variables (21). First, should an observed result be attributed to chance or is it real (statistical significance)? Second, if the result is real, how large is it (effect size)? Third, is the result large enough to be meaningful and useful (clinical or practical significance)? In this chapter, we treat clinical

significance as equivalent to practical significance.

Clinical Significance

The clinical significance of a treatment is based on external standards provided by clinicians, patients, and/or researchers. Judgments by the researcher and the consumers (clinicians and patients) regarding clinical significance should consider factors such as clinical benefit, cost, and side effects. Although there is no formal statistical test of clinical significance, we suggest using an effect size measure to assist in interpreting clinical significance. Each of these measures, however, has limitations that require the clinician to be cautious about interpretation.

Effect Size Measures

Statisticians have proposed many effect size measures. They fall mainly into three types or families: the *r* family, the *d* family, and measures of risk potency.

The *r* Family. One method of expressing effect sizes is in terms of strength of association, with statistics such as the Pearson product moment correlation coefficient, *r*, used when both the independent and the dependent measures are normally distributed. Such effect sizes vary between –1.0 and +1.0, with 0 representing no effect. This family of effect sizes also includes associational statistics such as the Spearman or Kendall rank correlation coefficients, and the multiple correlation coefficient (R).

The *d* Family. These effect sizes are used when the independent variable is binary (dichotomous) and the dependent variable is normally distributed. The *d* family effect sizes use different formulas, but they all express the mean difference in standard deviation units. Effect sizes for *d* range from minus to plus infinity, with zero indicating no effect; however, it is unusual to find *d* values in the applied behavioral sciences much greater than 1.

Measures of Risk Potency. These effect sizes are used when both the independent and the dependent variable are binary. There are many such effect sizes, but in this section we discuss five common ones: OR, RR, relative risk reduction (RRR), risk difference (RD), and NNT. ORs and RRs vary from 0 to infinity, with 1 indicating no effect. RRR and RD range from −1 to 1, with zero indicating no effect. NNT ranges from 1 to plus infinity, with very *large values* indicating no treatment effect.

AUC or Probability of a Superior Outcome. Finally we discuss an index that can be used when the independent variable is binary, but the dependent variable can be either binary or ordered. AUC stands for *area under the curve* but could be called the probability of a superior (better) outcome of one treatment over another. AUC

integrates many of the other effect size indices and is directly related to clinical significance. Kraemer et al. (22) and Grissom and Kim (23) provide more information on this relatively new effect size.

Unfortunately, there is little agreement about which effect size to use for each situation. The most commonly discussed effect size in the behavioral sciences, especially for experiments, is *d*, but the correlation coefficient, *r*, and other measures of the strength of association are common in survey research. In medical journals, an OR is most common.

In the remainder of this section, we discuss the use and interpretation of each of the above measures and discuss the advantages and disadvantages of each as indicators of clinical significance. In this discussion, we focus on positive association only—that is, effect sizes ranging from the value that indicates no effect to the value indicating maximal effect.

Interpreting *d* and *r* Effect Sizes

Table 3.1.1.12 provides general guidelines for interpreting the size of the effect for five measures discussed in this section. Cohen (5) provided research examples of what he labeled small, medium, and large effects suggested by *d* and *r* values. Most researchers would not consider a correlation (*r*) of 0.5 to be very strong because only 25% of the variance in the dependent variable is predicted. However, Cohen argued that when the two variables measure different constructs, an *r* of 0.3 is typical and 0.5 is about as large as correlations are found in applied behavioral sciences. When, as in test–retest reliability measures, the two variables measure the same construct, typical correlations are much higher, for example, 0.7 or more.

Cohen (5) also pointed out that effects with a *d* of 0.8 are “grossly perceptible and therefore large differences ….” Cohen’s medium size effect is “visible to the naked eye. That is, in the course of normal experiences, one would become aware of an average difference.” Kazdin and Bass (24), based on a review of psychotherapy research, found that *d* was approximately 0.8 when comparing a new active treatment against an inactive (treatment withheld) placebo. Comparing a new effective treatment with a usual or comparison treatment would produce a *d* of about 0.5.

The *d* and *r* guidelines in Table 3.1.1.12 are based on the effect sizes commonly found in studies in the applied behavioral sciences. They do not have absolute meaning; Cohen’s “large,” “medium,” and “small” were meant to be relative to typical findings in behavioral research in general. For that reason, we suggest using “larger than typical” instead of “large,” “typical” instead of “medium,” and “smaller than typical” instead of “small.” However, as suggested by the Kazdin and Bass (24) results, it is advisable to examine the research literature to see if there is information about typical effect sizes for those variables, in that context. The standards expressed in Table 3.1.1.12 then would need to be adjusted accordingly.

There are disadvantages of the *d* and *r* effect sizes as measures of clinical

significance. First, they are relatively abstract, and consequently may not be meaningful to patients and clinicians, or even to researchers. They were not originally intended to be indices of clinical significance and are not readily interpretable in terms of how much *individuals* are affected by treatment.

Interpreting Measures of Risk Potency

Clinicians must make categorical decisions about whether or not to use a treatment (medication, therapy, hospitalization), and the outcomes also are often binary. For example, a child is classified as having ADHD or not, or being at risk for some negative outcome or not. In comparing two treatments, a positive outcome might indicate that the patient is sufficiently improved (or not) to meet the criteria for a clinically significant change. These binary decisions and outcomes provide data in a 2 × 2 contingency table. In some cases, a 2 × 2 table results when initially continuous outcome data are dichotomized (when responses on an ordered outcome measure in a clinical trial are reclassified as "success" and "failure"). Such dichotomization not only results in a loss of information, but, dichotomizing can result in inconsistent and arbitrary effect size indices due to different choices of the cut point or threshold for failure.

Odds Ratio. OR is the most commonly reported of these measures. However, a major limitation of the OR as an effect size index is that the magnitude of the OR may approach infinity if the outcome is rare or very common, even when the association is near random or no effect. The magnitude of the OR varies strongly with the choice of cut point.

Risk Ratio. Again, the choice of cut point and which RR (failure or success) is chosen change the magnitude of the RR, making it hard to interpret. Because the RR may approach infinity when the risk in the denominator approaches zero, there can be no agreed-on standards for assessing the magnitude or clinical significance of RR.

TABLE 3.1.1.12

INTERPRETATION OF THE STRENGTH (EFFECT SIZE) OF A POSITIVE RELATIONSHIP

	The *d* Family:	The *r* Family	2 × 2 Associations		
General Interpretation of the Strength of a Relationship	*d*	*r*	*AUC*	*RD*	NNT
Much larger than typical	≥1.00	≥.70	≥76%	≥52%	≤1.9
Large or larger than typical	0.80	0.50	71%	43%	2.3
Medium or typical	0.50	0.30	64%	28%	3.6
Small or smaller than typical	0.20	0.10	56%	11%	8.9

Note: We interpret the numbers in this table as a range of values. For example, *d* greater than 0.90 (or less than –0.90) would be described as much "larger than typical," in the applied behavioral sciences, *d* between say 0.70 and 0.90 would be called "larger than typical," and *d* between say 0.60 and 0.70 would be "typical to larger than typical." We interpret the other columns similarly. AUC, Area under the curve, or probability of a superior outcome; RD, Risk difference; NNT, Number needed to treat.

Relative Risk Reduction. RRR can vary between 0 and 1.0. Because the "failure" RRR may be very small when the "success" RRR is large, RRR is difficult to interpret in terms of clinical significance, and there are no agreed-upon standards for judging its magnitude.

Risk Difference. RD, also called absolute risk reduction (ARR), can vary from 0% to 100%. When the RD is near zero, it indicates near random association. If the success or failure rates are extreme, the RD is likely to be near 0%. It is troublesome in terms of interpreting clinical significance that the RD is often very near zero when the OR and one of the RRs are very large.

Number Needed to Treat. NNT is a relatively new measure that has been recommended for improving the reporting of effect sizes, but it has not yet been widely used. NNT is the number of patients who must be treated to generate one more success or one less failure than would have resulted had all persons been given the comparison treatment. Mathematically, NNT is the reciprocal of the RD. A result of 1.0 means the treatment is perfect, that every treatment subject succeeds and every comparison subject fails. An NNT greater than 1.0 means that the treatment is less than ideally effective, and the larger the NNT, the relatively less effective the treatment.

AUC or the Probability of a Superior/Better Outcome. This relatively new effect size might substitute for either *d* family measures or measures of risk potency. It represents the probability that a randomly selected participant in the treatment group has a better result than a randomly selected one in the comparison group. As shown in Table 3.1.1.12, one can define guidelines for interpreting AUC that correspond to those for *d*. For example, a medium or typical effect size of $d = 0.5$ corresponds to AUC = 64%. Thus, when comparing a treatment subject against a comparison subject, 64% of the time the treatment subject would have a better response.

AUC is of special interest because it can be computed based on clinical judgments alone. One could randomly select pairs of subjects, one of each pair in the treatment and one in the comparison group, and submit their clinical records to experts with group membership masked. The experts would then be asked which of the two had a better outcome. The proportion of the pairs for which the experts said that the treatment group subject was better off is an estimate of AUC.

Conclusion

Nuovo et al. (25) pointed out that the Consolidated Standards on Reporting Trials (CONSORT) recommends reporting the NNT or the RD. However, often RD can seem unimpressively small, and NNT may seem very large, suggesting very little effect of treatment. In many such cases with small RD or large NNT, one of the RRs and one of the RRR measures and, most of all, the OR can give an inflated impression of the size of the effect, thus exaggerating apparent clinical significance. For this reason, our preferred effect size for understanding clinical significance would tend to be AUC (the probability of a superior outcome), but remember that *d*, NNT, and RD are all mathematically equivalent and can be converted to AUC.

We have provided some general guidelines for interpreting measures of clinical significance. It is not possible, however, to provide any fixed standards that a clinician could use to conclude that an effect size was clinically significant. It makes a difference whether the treatment is for a deadly disease or for the common cold, and whether the treatment is risky and costly or safe and free. The context in which an effect size is used matters in interpreting the size of the effect; the effect size only facilitates consideration of clinical significance.

EVALUATING THE DESIGN AND METHODS OF A RESEARCH STUDY

This concluding section provides an overview of the evaluation of *research validity,* the validity of the design and methods of a study as a whole.

Research Validity Versus Measurement Reliability and Measurement Validity

It is important to distinguish between evidence for the merit or worth of the whole study (*research validity*) as opposed to evidence in support of the quality of a specific instrument or test used in a study (*measurement validity*). Figure 3.1.1.7 shows that measurement reliability and validity (the upper two boxes) are different from, but related to, research reliability and validity (lower boxes), and the figure shows how all four fit into an overall conception of reliability and validity. The horizontal arrow indicates that measurement reliability is a necessary prerequisite for measurement validity (a measure cannot provide evidence for validity if it is not consistent/reliable). The vertical arrow indicates that the validity of a whole study depends to some extent on the reliability and validity of the specific measures or instruments used in the study.

Rating Scales to Evaluate Research Validity

A good study should have moderate to high internal *and* external validity. However, it is hard, in any given study, to achieve this goal. Using our research validity framework, a reader would evaluate a study from low to high on each of the four scales or dimensions shown in Figures 3.1.1.8 and 3.1.1.9. In Morgan et al. (3), we provide a comprehensive framework for evaluating the research validity of an article, including four additional rating scales.

Internal Validity

The top part of Figure 3.1.1.8 indicates the key features we use to rate the dimension of *equivalence of the groups on participant characteristics.* The bottom of Figure 3.1.1.8 shows the five issues that we use to rate the *control of experiences and the environment during the study,* that is, contamination.

External Validity

External validity broadly defined asks about generalizability to other populations, settings, treatment variables, and measurement variables. If a study is not rated high on external validity, the author should at least be cautious about generalizing the findings. We use the three issues in the top of Figure 3.1.1.9 to evaluate *population external validity* and the five issues listed in the bottom part of Figure 3.1.1.9 to evaluate *ecologic external validity,* whether the setting, testers, procedures, and timing of the study are natural and, thus, whether the result of the specific study can be generalized.

ACKNOWLEDGMENTS

This chapter draws heavily on our textbooks, *Understanding and Evaluating Research in Applied and Clinical Settings* (3) and our current text Research Methods in Applied Settings (10). We appreciate permission to reprint or adapt from those books all the tables and figures used in this chapter.

RELIABILITY Stability or Consistency	**VALIDITY** Accuracy and Representativeness
Measurement (or test) reliability The participant gets the same or a very similar score from a specific *test*, *observation*, or *rating* when it is used for a similar purpose with a similar population. →	**Measurement (or test) validity** The score accurately reflects/measures what it was designed or intended to measure when used for a similar purpose with a similar population. ↓
Research (or study) reliability If repeated, the *study* would produce similar results. This is called *replication*. Meta analysis examines several similar studies in part to examine the consistency of their results.	**Research (or study) validity** The results of the study are accurate and generalizable. Two major dimensions of the *validity of a study* are: ▪ **Internal validity**—Strength of design. If high, one can make valid interferences about causes. • Equivalence of groups on participant characteristics. • Control of extraneous experience and environmental variables ▪ **External validity**—If high, the results may generalize to other populations, settings, and variables. • Population validity • Ecological validity

FIGURE 3.1.1.7. Relationships and differences between measurement reliability and validity and research reliability and validity.

INTERNAL VALIDITY

Equivalence of Groups on Participant Characteristics

Based rating on:

a) Were the participants randomly assigned to the groups?
b) If not, were there adequate attempts to make groups similar (e.g., ANCOVA) or *check* similarity on a *pretest?*
c) If no randomization, were there adequate attempts to make groups similar or check similarity on *other key variables*?
d) Was retention during the study high and similar across groups?

LOW	MEDIUM	HIGH
Groups very different, marked differential attrition	Some attempts to equate groups or groups found to be similar	Random assignment to groups and low attrition

Control of Experiences and Environment Variables (Contamination)

Based rating on:

a) Was the study conducted in a controlled environment (e.g., a lab)?
b) Were extraneous variables that could affect one group more than the others controlled? Did the groups have the same type of environment?
c) Was there a no treatment group (placebo) or usual treatment group?
d) Were extraneous variables that could affect all groups and obscure the true effect controlled?
e) Were attempts to reduce other extraneous influences adequate?

LOW	MEDIUM	HIGH
Extraneous variables not controlled, no comparison group (field setting)	Attempts to control experiences and environment	All extraneous variables controlled, eliminated or balanced (controlled lab)

FIGURE 3.1.1.8. Rating scales to evaluate the internal validity of the findings of a study.

EXTERNAL VALIDITY

Population

Base rating on:
1) Representativeness of accessible population vis à vis theoretical population
2) Adequacy of sampling method from accessible population
3) Adequacy response/return rate

LOW	MEDIUM	HIGH
Actual sample unrepresentative of the theoretical population	Some attempt to obtain good sample	Actual sample representative of theoretical population

Ecological

Base rating on:
1) Naturalness/representativeness of setting/conditions
2) Adequacy of rapport with testers/observers
3) Naturalness of procedure/tasks
4) Appropriateness of timing and length of treatment (if any)
5) Extent to which results are *not* restricted to a specific time in history

LOW	MEDIUM	HIGH
Unnatural setting, tester, procedures and time	Somewhat artificial (e.g., questionnaire)	Natural setting, tester, procedures and time

FIGURE 3.1.1.9. Rating scales to evaluate the external validity of the findings of a study.

Earlier versions of the tables, figures, and text were published as a series of articles, "Clinicians' Guide to Research Methods and Statistics," published between 1999 and 2003 in the *Journal of the American Academy of Child and Adolescent Psychiatry* (JAACAP) by Lippincott Williams & Wilkins. We especially appreciate the critiques and statistical advice on the JAACAP series from Helena Chmura Kraemer, professor of biostatistics at the Stanford University Medical School.

We also acknowledge the advice and encouragement of Andrés Martin, and we thank the Developmental Psychobiology Research Group (DPRG), Department of Psychiatry, University of Colorado School of Medicine, for support over many years. Dr. Harmon's unexpected death was a loss to us personally, and to the profession of child and adolescent psychiatry. We could not have completed the chapter without the word processing skills of Alana Stewart and Jessica Gerton.

APPENDIX: PARTIALLY SIMILAR TERMS FOR DIFFERENT CONCEPTS[1]

- Cronbach's *alpha* ≠ *alpha* (significance) level

- *Dependent* variable ≠ *dependent* samples design or statistic
- *Discriminant* analysis ≠ *discriminant* evidence for measurement validity
- *Factor* (i.e., independent variable) ≠ *factor* analysis
- Factorial *design* ≠ *factorial* evidence for measurement validity
- *Independent* variable ≠ *independent* samples
- *Levels* (of a variable) ≠ *level* of measurement
- *Odds* ratio ≠ *odds*
- *Outcome* (dependent) variable ≠ *outcome* (results) of the study
- Research *question* ≠ questionnaire *question* or item
- *Random* assignment of participants to groups ≠ *random* assignment of treatments to groups
- *Random* assignment (of participants to groups) ≠ *random* selection (or sampling of participants to be included in the study) ≠ random order
- Odds *ratio* ≠ risk *ratio*
- *Related* samples design ≠ variables that are *related*
- Random *samples* ≠ paired/related *samples* ≠ independent *samples*
- Measurement *scale* ≠ a rating *scale* ≠ summated/composite *scale*
- *Theoretical* research ≠ *theoretical* population
- Measurement *validity* ≠ research *validity*

CHAPTER 3.1.2 ■ EVIDENCE-BASED PRACTICE AS A CONCEPTUAL FRAMEWORK

JOHN HAMILTON

INTRODUCTION

Child and adolescent psychiatry is a unique discipline, often practiced within the context of a multiprofessional organization. Hence, this chapter begins with how various professional groups use the phrase "evidence based." It then proceeds to show how evidence-based processes achieve results significantly different than usual practice. It continues with common objections to EBP, with a rebuttal for each. The second part of this chapter presents selected elements of EBP within the context of pediatric mental health: tips on searching the most relevant databases, diagnostic approaches consistent with EBP, choosing a treatment, developing local data, and ideas about developing evidence-based systems. The definition of evidence-based practice used here is *feasible efforts to align clinical practice with valid, reliable, and relevant empirical results regards assessment and treatment in youth with the goal of reducing symptoms and improving functional outcomes—promptly, for extended periods, inexpensively and with few errors or adverse events using processes chosen by the youth and his or her parents or guardian.* This definition is idealistic—hence the adjective *feasible*—but it is useful in outlining the multiple and sometimes conflicting goals of EBP.

THREE STREAMS, ONE RIVER

Varied authors and groups have used "evidence-based" (EB) as a modifying phrase. Evidence-based practice, or EBP (1,2), is the term used here, but there is also evidence-based medicine, or EBM (3), evidence-based services, or EBSs (4), and evidence-based treatments, or EBTs (5). The phrase "empirically supported treatments," or ESTs, is often used interchangeably with EBT (6). To oversimplify, there are three groups. The first group, using the term EBM, is often associated with medication issues and child psychiatrists. The second group, using the term EBT, is associated with psychologists, psychosocial treatments, and the American Psychological Association (APA). The third group, EBS, is associated with systems striving to better use empirical results to improve outcomes. In this chapter, when we refer to EBP, we are including all three groups. These three groups share a common interest in making use of empirical data, both "local" data regards our own patients as well as data from published studies. Combining the work of all three groups produces a powerful flood of ideas.

There is considerable overlap between EBM, EBT, and EBS, but each retains its distinct flavor. EBM authors often focus on changing individual practitioner behavior. For example, EBM tries to interest practitioners in researching "answerable questions" regarding individual patients. Often examples used involve medications. Many well-known EBM leaders like David Sackett are epidemiologists or internists. On the other hand, EBT authors tend to focus more on studying specific manualized psychosocial treatments. EBT authors are often university-affiliated psychologists who study the effectiveness of a psychosocial intervention for a specific disorder, or who distill core elements of effective treatments from multiple studies into modules which can be employed flexibly with a multidisorder focus (7). They also study how a psychosocial intervention "travels" when it is "exported" to sites other than where it was developed. Finally, evidence-based services (EBSs) is a term used by clinicians in delivery systems trying to improve outcomes by better use of empirical evidence (8). In EBS a consensus-building group of providers, administrators, and consumers agrees on a menu of effective interventions including both EBTs and medications. These three empirical approaches are summarized in Table 3.1.2.1. The term evidence-based practices, or EBPs, used here is an umbrella term for processes based on all three groups while valuing patient preference and clinical expertise as well. EBP welcomes the use of clinical expertise, for example, in formulating the context of symptoms (9). And, while including both medication and psychosocial interventions, EBP is neutral in choosing between them, an advantage on a multidisciplinary team.

TABLE 3.1.2.1

EVIDENCE-BASED MEDICINE (EBM), EMPIRICALLY SUPPORTED TREATMENTS (ESTs), AND EVIDENCE-BASED SYSTEMS (EBS)

	EBM	EST[a]	EBS
Origins	Many ideas developed at McMaster University in Ontario, Canada	American Psychological Association Task Force 12	State of Hawaii Child and Adolescent Mental Health Division (CAMHD)
Central Ideas	PICO (Population/Intervention/Control or Comparison/Outcome) based on epidemiologic thinking is core idea; "Bringing the literature to the bedside"	Focus on efficacy and effectiveness of well-defined psychosocial interventions; laboratory–clinic gap a major hurdle	Feasible but proven treatments; extensive use of locally generated data; systemwide consensus on effective interventions
Frequent Members	University-based physicians	University-based psychologists	Large systems wanting improved results

[a]Also called Evidence-Based Treatments.

Significant boundaries between child psychology and child psychiatry have shaped these three streams of empiricism. Child psychologists and child psychiatrists typically belong to different professional organizations, attend different conventions, publish in different journals, and occupy different niches in clinical organizations such as state clinics or hospitals. These different worlds naturally evolve different ways of thinking, sometimes referred to as cognitive boundaries (10). In fact, the prevailing paradigm in each discipline may be so different that each discipline has distinct cognitive assumptions and may advance different claims to knowledge. At their worst, boundaries can be sufficiently extreme that there is no common ground for productive dialogue (11).

EBP is a helpful antidote to the tendency of practitioners to identify with a particular discipline or treatment. For example, a practitioner may think of himself as primarily a psychopharmacologist, or as a family therapist, a play therapist, a behavior therapist, or as an expert in delivering a specific manualized therapy. EBP as conceived here, on the other hand, is not attached to a specific treatment modality or profession. Instead, EBP chooses those feasible treatments proven in the most valid studies to deliver the most rapid, complete, and long-lasting improvement in functioning and symptoms with the least harm. A commitment to EBP therefore significantly changes the identity of practitioners: A commitment to finding and using both published and "local" evidence becomes a central value.

In a multidisciplinary team, the processes of making a diagnosis, choosing a treatment, and assessing its results are all significantly different in a team committed to EBP than in a team proceeding "as usual." Table 3.1.2.2 lists a chain of clinical processes fundamental to EBP, and highlights differences between the EBP approach and usual practice in defining the clinical population, in choosing an intervention, and in evaluating its effects relative to a comparison or control group. This order is the familiar PICO format derived from epidemiology: Population, Intervention (or Exposure), Control (or Comparison), and Outcome. Of course, a solo practitioner can also use many of these processes. For example, both the well-known PubMed site as well as the Internet site for the Journal of the American Academy of Child and Adolescent Psychiatry offer extensive resources for searching answerable questions. A major issue for practitioners, however, is how to offer ESTs that often require extensive training. To be competent to deliver Parent management training (PMT) for Oppositional Defiant Disorder, for example (12), or Cognitive Behavioral Treatment or Interpersonal Therapy for depression (13) requires training. Yet a practitioner may choose to obtain training in those ESTs which will be most useful in the practice she has developed. Informal subspecialization among community therapists is also an option.

WHY BOTHER? COMMON OBJECTIONS TO EBP, WITH

REBUTTALS

Objections to EBP are inevitable. Here are some common ones; each is followed by a rebuttal.

There is not much evidence in child psychiatry anyway.

A variant of this complaint is *There aren't RCTs for everything.* Although this is certainly true, it is also true that there are a lot more now than when this objection was most popular. A wave of RCTs in the past decade means often there is a relevant RCT. Table 3.1.2.3 shows the increase in the number of RCTs in youth with ADHD or an anxiety disorder or depression or psychosis, searched as MeSH terms, published in PubMed (14). The growth in systematic reviews and meta-analyses has been similar. In addition, the EBP practitioner is committed to the judicious use of the most valid and relevant evidence available, not just RCTs, using a hierarchy of evidence to minimize bias, and RCTs are high up in that hierarchy. But if only case reports exist, then the EBP approach is to use them as evidence.

How closely are therapeutic relationship variables and outcomes associated in youth psychotherapy? Studies of the relationship between treatment outcomes and therapeutic alliance show a significant yet modest effect. A meta-analysis of individual psychotherapy with youth shows a weighted mean correlation of 0.22 (k = 16, n = 1,306, $p < 0.001$) between alliance and outcome (CI = +/−0.06) (15). Moreover, it is the changes in TA that robustly predict reduction in youth symptoms rather than initial alliance (16). And in community-based child therapy, a strong therapeutic relationship supported continuing to attend sessions (17). In addition, the parent–therapist alliance was associated with reductions in internalizing psychopathology, while a close child–therapist alliance assessed during treatment was associated with a reduction in anxiety symptoms (18,19).

In summary, the therapeutic alliance matters in promoting attendance, in dealing with externalizing, and internalizing disorders, as well as in community-based child therapy, and change in the therapeutic alliance robustly predicts symptom reduction.
The therapist is an artist, and psychotherapy is a subjective human encounter with a unique youth that can never be captured in an RCT.

At least some therapists object to EBP because it examines outcomes for groups of youths and in the process loses the unique aspects of each individual youth. According to this argument, EBP conclusions based on groups of youth fail to respond to each youth's uniqueness since no two youth share exactly the same genetic makeup, cultural heritage, social circumstances, developmental history, and family background. Yet it is a caricature of EBP interventions that they are applied indiscriminately without any interest in the individual. Consider an EBP psychosocial intervention as having a hard core but a soft exterior (20): Whereas the outside can be modified and individualized to make it easy to swallow, the hard inner core contains the essential components which create change.

TABLE 3.1.2.2

FUNCTIONS AND PROCESSES: TREATMENT AS USUAL VERSUS EBP

Function or Process	Treatment as Usual	Team Committed to EBP
Defining characteristics of clinical population at intake	Highly variable, narrative intake note DSM-IV as guide	Functioning and psychopathology measured with defined instruments while clinical interview establishes alliance and context of symptoms
Defining primary outcome variable(s)	Usually not done	Preference for choosing primary outcome variable(s) at time of evaluation (or assessment)
Choosing an intervention	Chosen on basis of familiarity, ease of use, often clinician specific	Pyramid of evidence has central role, evidence updated regularly
Evaluating local effect of interventions proven elsewhere	Often ignored	Always an issue, addressed via collecting local data
Collecting and making use of composite local diagnostic and outcome data	Rarely done	Always done, including benchmarking results to compare with natural history and published outcomes
Use of outcome data to inform provider, consumer, and administrator	Case outcome often not tracked with reliable measure; minimal aggregate outcome data	Provider, administration, consumer all interested in outcome data, individual and aggregate
Teaching staff EBP	Minimally structured case conferences or traditional supervision	Staff learns EBP in programwide projects and has access to EBP instruction Culture welcomes fidelity monitoring and feedback from data
Linking providers to the literature	Conferences and reading	Conferences and reading; high-speed Internet connections to most useful databases; answerable questions searched often
Overall team culture	Multiple general practices; each clinician on her own	Clinicians specialize often; empirical results direct teamwide consensus

In addition, newer generations of ESTs are sensitive to the criticism that a manualized treatment needs to be individualized as well as lively and engaging. Consider a recent study of collaborative problem solving in moody children with ODD (21). The design of this study allows for therapists providing the intervention to determine session content on the basis of their assessment of the clinical needs of the child and family. Other authors have also called for blending creativity and flexibility into a manualized treatment to allow individual variation within a defined intervention (22).

TABLE 3.1.2.3

INCREASING RCT EVIDENCE IN CHILD PSYCHIATRY, 1992–2015: PUBMED RCTs FOR ADHD, ANXIETY OR DEPRESSIVE DISORDER, OR PSYCHOSIS

Number of RCTs, 1992–2015
Finally, the first paradigm of the therapist as artist, working with the unique patient to create a unique solution, and the second paradigm of the therapist as adherent to the results of the best science, may be growing toward each other in recent years. For example, some recent EBM articles have softened their position toward the value of experience and clinical judgment (23), while the APA has hardened its position about the importance of randomized trials (24). And efforts to develop strategies based on individualizing treatments supported by research, called personalized interventions, blur usual distinctions (25). Both perspectives can be valued by a practitioner sensitive to multiple inputs: patient preference, his own experience, the nuances of each child, and the most valid available evidence.

THE CASE FOR EBP

Community care of clinically referred youth too often shows unimpressive results. Two studies have shown that, in real-world practice settings, it is difficult for child mental health interventions to show an effect compared to a control group (26,27). In the first, a randomized study by Bickman et al. (26), one arm of the study received an increase in resources. Interviews were conducted for 2 years following collection of baseline data. Results in measures of symptoms and functioning showed that, while the arm with a considerable increase in resources did have improved access to care and in fact actually received more care, these access differences did not translate into improved clinical outcomes. In addition, children who did not receive any services improved at the same rate as treated children. This sobering conclusion is supported by Weisz and Jensen's review of the effectiveness of both medication and psychosocial intervention in the context of the real world of caring for clinically

referred youth. The authors note that evidence, where available, on the effectiveness of such treatment is minimal when compared to the large body of evidence on efficacy. It seems reasonable to conclude that such null results suggest the need for change.

The evidence-based system in Hawaii's clinics appears to have improved outcome results.

In contrast to the sobering conclusions of these null results, committed efforts to build an evidence-based system of care in Hawaii's Child and Adolescent Mental Health Division (CAMHD) appear to have improved outcomes. This story begins in 1994 when federal courts charged the state with establishing a system of care to provide effective mental health and special education services for children and youth as required by federal law (8). The initial system responses to the court's decree included planning efforts and increases in service capacity, allowing more youth to access a wider variety of services, as well as increased quality monitoring and more interagency coordination. The statewide quality monitoring included basic quantitative feedback; this feedback demonstrated more youth being served by more services at a higher cost. Since stakeholders wanted assurances of efficiency, the focus turned to asking whether the increase in resources had led to improved symptomatic and functional outcomes with empirical results as the arbiter. In addition, CAMHD's leaders wanted the system to develop in a way that frontline decisions about patient care were based on the best available evidence. They focused, therefore, on linking the best and most relevant evidence to clinical decisions (8).

To accomplish this linking, the Hawaii Department of Health organized a task force on empirical services in October, 1999 (6); the only requirement for membership was, and remains today, regular attendance and willingness to read and review studies. Its membership has included clinicians from several disciplines, university faculty, parents, administrators, and CAMHD employees. This task force is charged with conducting ongoing multidisciplinary evaluation of psychosocial interventions for common disorders using methodology developed in the Clinical Division of the APA. Additional topics can be reviewed as well, such as the efficacy of seclusion procedures. Each search uses a structured methodology; results are evaluated with a five-level system ranking the efficacy and effectiveness of each intervention. (Effectiveness is based on the performance of the intervention under naturalistic, or real-world, conditions.) The task force begins with a literature-based approach but its diverse constituency tempers the results to fit local conditions.

The result of the task force's work has been a "menu" of recommended treatments distributed to clinicians on a single sheet of blue paper, creating the nickname "blue menu," summarizing recommended psychosocial treatments. It is also posted on the Internet. A one-page review of the task force's conclusions regarding psychotropic medications' efficacy and effectiveness for the children of Hawaii is also distributed

and posted on the Internet. Both are updated biennially.

CAMHD also tracks its own results at case, clinic, and system levels wide as well with the Child and Adolescent Functional Assessment Scale, or CAFAS (28), the Child Behavior Check List, Teacher Report Form, and Youth Self-Report (29). Following individual cases allows clinical staff to identify whether or not a youth is improving. Documented ongoing progress leads to the recommendation of continuing the present treatment. If a youth is not improving, the clinicians can reexamine whether there is a problem in treatment selection; if so, a more favorable intervention is sought (8).

Quarterly outcomes based on parent, teacher, and clinician reports for Hawaiian youths treated improved significantly during the years 2001 through 2004, years when the system was actively moving toward EBP (30). The slope of mean improvement in functioning as rated by the CAFAS showed a 146% increase; the slope of mean improvement in CBCL showed a 271% increase, and the TRF a 50% increase over the course of the 3-year period (30). The proportion of youth showing a pattern of improvement during the service episode based on CBCL data rose from 54.7% to 68.2%, based on TRF data from 50.7% to 58.6%, and based on the CAFAS from 66.5% to 69.0%.

These results are consistent with the hypothesis that implementing EBSs significantly impacts both functional outcome and symptomatic outcome. Furthermore, the results are large and clinically significant. Whether the changes in functioning improvement and symptom reduction stabilize here or continue to improve requires continued study. Although this study did not control for such potentially confounding variables as diagnostic mix, gender, or ethnicity impacting the results, it nevertheless shows consistent and large results across three separate informant groups—parent, teacher, and clinician.

Rather than using manualized psychotherapies to integrate the evidence into practice, use “modules” of effective psychotherapy—central elements of multiple randomized trials distilled into a core practice, such as “exposure” or “relaxation training” or “psychoeducation.”

In a randomized trial comparing usual care and an approach using modules—central elements of multiple randomized trials, distilled into modules—the modular approach significantly outperformed usual care as well as standard evidence-based treatments based on manuals proven in RCTs (7). A limitation to generalizability of the study’s results to many clinics is the minimal use of combined psychotherapy and pharmacotherapy.

If EBP seems, therefore, well worth the effort, let’s turn now to its core ideas.

CENTRAL CONCEPTS IN EBP

Number needed to treat, number needed to harm

The number needed to treat, or NNT, for any given intervention in a defined population, is the number of patients we need to treat with the intervention in order to prevent one additional bad outcome (31). This is calculated as follows:

NNT = 1/(Proportion of subjects in control group with bad outcome minus proportion of subjects in intervention group with bad outcome)

The denominator in the NNT equation is called the absolute risk reduction (ARR). Hence, a brief version of the formula is:

$$NNT = 1/ARR$$

As an example of NNTs, consider the Treatment for Adolescents with Depression Study (TADS). The "bad outcome" chosen was a failure to score either much improved or very much improved when assessed by an independent rater using the Clinical Global Impression (CGI) scale. Using this definition of bad outcome, 39.4% of subjects in the fluoxetine cell had a bad outcome versus 65.2% of subjects in the placebo cell. Thus:

$$NNT = 1(0.652 - 0.394) = 1/0.258 = 3.87$$

Therefore the NNT reported for fluoxetine alone was 4, with 95% CI 3 to 8 when response is defined as a CGI score of much improved or very much improved at the end of treatment. The calculated NNT for combined treatment with CBT and fluoxetine using the identical definition of response was 3, with 95% CI 2 to 4 (32). The value of adding CBT to fluoxetine is evident not only in the improved NNT but also in the much narrower confidence intervals. Table 3.1.2.4 calculates NNTs in child and adolescent psychiatry for a variety of other disorders as well. Note that, in general, these NNTs hold up well in comparison with many standard interventions in medicine: Sackett et al. (31) note that the NNT for preventing diabetic neuropathy with 6.5 years of intensive insulin treatment is 15, and that the risk of preventing a death over 5 weeks using streptokinase infusion in patients with acute myocardial infarction is 19. The NNTs in this table are a reflection of the progress made in recent decades in child and adolescent psychiatry.

TABLE 3.1.2.4

ABSOLUTE RISK REDUCTION (ARR) AND NUMBER NEEDED TO TREAT (NNT)[a] FOR SELECTED COMMON DISORDERS IN CHILD AND ADOLESCENT PSYCHIATRY

Disorder/Population	Intervention	Metric	Respond (%) Treatment	Respond (%) Control	ARR	NNT ≤
ADHD (MTA) (33)	Medication Behavioral R_x	SNAPIV[PT] <1.0[b]	56 34 68	25	31 9 43	3 11 2–3

MDD/Age 12–17	Both Community Fluoxetine CBT	CGI[c]	60.6 43.2		25.8 8.4	4 12
Outpatient TADS Team (32)	Fluox + CBT Placebo		71.0	34.8	36.2	3
MDD (34)	CBT Supportive Rx	BDI <9[d] 3 wks in a row	64.7	39.4	25.3	4
POTS (35)	CBT alone Sertraline alone CBT + sertraline Placebo	CY-BOCS <10	21.4 9.3 21.5 1.4 21.6 3.6	3.6	17.8 5.7 17.9 7.8 17.10 0	3 6 2
ODD, Conduct Disorder (36)	PMT alone PSST alone Combined	CBCL Total Behavior Problems ≤90	38.9 33.3 64.0	Assume 0.0[e]	38.9 33.0 64.0	3 3 2
Mania (37)	Divalproex + quetiapine Divalproex + placebo	YMRS	87	53	34	3
Recurrent MDD (38)	Fluoxetine Placebo	Relapse over 32 wks	CDRS-R >40 + 2 wks doing poorly[f]	34 60	16	7

ADHD, attention deficit hyperactivity disorder; BPR, brief psychiatric rating—children; CBT, cognitive behavioral therapy; CD, conduct disorder; CDRS-R, children's depression rating scale—revised; CY-BOCS, children's Yale-Brown obsessive-compulsive scale; MDD, major depressive disorder; MTA, multimodal treatment of ADHD; ODD, oppositional defiant disorder; PMT, parent management training; POTS, Pediatric Obsessive-Compulsive Disorder Treatment Study; PSST, problem solving skills training; TADS, Treatment of Adolescent Depression Study; YMRS, Young Mania Rating Scale.

[a]How the NNT is calculated varies from study to study, and this needs to be considered when understanding what NNT means for that study (see below).

[b]SNAP-IV, Swanson, Nolan, Pelham, Version IV, parent and teacher rating scale, mean of parent and teacher score.

[c]CGI-Clinical Global Impression score, evaluator-rated, improved or very much improved.

[d]Control received nondirective supportive therapy.

[e]No control used; since the natural history of conduct disorder is that symptoms tend to persist over time, the assumption of no change in symptoms was assumed as the best estimate for a control (39).

[f]Or physician rater's impression of relapse.

By convention, NNT is always a whole number, rounded off to an integer. Note that NNT is impacted by several factors in addition to the effect of the intervention itself. First, how recovery is defined affects NNT; choosing a cutoff that makes it "easy" to achieve recovery produces a lower NNT. Second, how many in the control group spontaneously recover affects NNT; the more spontaneous recoveries in the control group, the more difficult it is to achieve a low NNT. Third, when the data are "sliced" to compare the intervention and comparison group may affect the NNT; time periods when the control and intervention groups diverge the most, such as longer follow-up times, produce lower NNTs. Ideally, NNTs are presented with 95%

confidence intervals.

Note that classically, the NNT is calculated relative to a placebo group. However, some studies are purposefully designed without a placebo group for ethical or other reasons. Studies in Table 3.1.2.4 without a placebo arm are the MTA study, the Brent 1997 study, and the Kazdin 1992 study. Consider, for example, the MTA study, and the calculated NNT of 3 in the medication arm. This means it would be necessary to treat about 3 children with the carefully crafted medication management strategy in order to get 1 to reach the defined threshold for improvement who would not have reached that threshold if he had been treated in the community treatment arm. These studies, therefore, set an upper bound on the true NNT: the NNT relative to a true placebo, the formal definition of NNT. Therefore this column is indicated NNT ≤. The only exception to the upper bound rule is the study of PMT and PSST where no change is assumed as a control in the calculation, based on the natural history of the disorder.

The number needed to harm (NNH) is a useful measure of the frequency of undesired consequences from a treatment, and is calculated the same as the NNT, but based on the proportion of patients with the undesired consequence in the intervention group compared to the comparison group. For example, in the TADS study, 3.7% of the fluoxetine alone group had either an elevated mood, mania, or hypomania during the study, versus 1.78% of the placebo group (32). To put this number in context, however, it is important to note that adolescents with known bipolar disorder were excluded, and so were adolescents hospitalized for dangerousness to self or others within 3 months of consent or were deemed "high risk" for suicide. (The NNH regards a mood "switch" for fluoxetine in this sample is therefore 53.) In the same study, the adverse events of irritable or depressed mood including a worsening of depression or irritability or hypersensitivity or anger occurred in 4.6% of the fluoxetine group and 9% of the placebo group, generating an NNH of 22. One or more adverse events occurred in 18.3% of youth in the fluoxetine arm and 8.0% in the placebo group, for an NNH of 10 for at least one adverse event.

Both NNT and NNH are ideally stated with 95% confidence intervals. In practice, few parents wish to hear technical discussions of sample size and confidence intervals. Nevertheless, the issue of confidence intervals can be included with verbal statements like "this has been studied so well we are quite certain about this" if the confidence intervals are narrow. Alternatively, for large confidence intervals, the clinician may state something like "the studies so far have not been definitive, so there's a big range of possible answers once this gets studied in more detail."

Hierarchies of Evidence

If potential "evidence" in EBP is defined as "any empirical observation about the apparent relation between events," (40) then it is useful to have a system for rating

such empirical observations about the relation between events, with the least biased studies at the top. In EBP, this is done by creating a vertical hierarchy: Each step of the hierarchy represents a certain level of bias within the research design. With each step downward on the hierarchy, more bias is introduced.

TABLE 3.1.2.5

A HIERARCHY OF STRENGTH OF EVIDENCE FOR TREATMENT DECISIONS

N of 1 randomized controlled trials
Systematic reviews of randomized trials
Single randomized trial
Systematic review of observational studies addressing patient-important outcomes
Single observational study addressing patient-important outcomes
Physiologic studies
Unsystematic clinical observations

(From Guyatt G, et al.: Introduction: the philosophy of evidence-based medicine. In: Guyatt G, Rennie D (eds): *Users' Guides to the Medical Literature: A Manual for Evidence-Based Clinical Practice*. Chicago, IL. AMA Press, 3–12, 2002, with permission.)

The hierarchy of evidence from EBM in Table 3.1.2.5 shows the weight given randomized controlled trials and the even higher weight given systematic reviews of such trials. The N of 1 randomized controlled trial is at the very top position, but it is useful only for certain kinds of interventions, such as a stimulant medication dose which can be randomized to "on" or "off" in the same patient during subsequent time periods. For stimulant dose trials, N of 1 trial data are very good evidence indeed, since they come directly from the patient of interest and concern the treatments under consideration. Unfortunately, however, most other treatments cannot be so easily studied in an N of 1 trial.

Guyatt's "classical EBM" hierarchy of evidence is only a beginning, however, in choosing a treatment. The APA's clinical division (Division 12) has established a hierarchy of evidence for rating psychosocial treatments with several levels. "Well established" requires two independent randomized trials with active controls. "Probably efficacious" requires 1 randomized trial with an active control or two trials with wait-list controls (6). Yet many questions remain in either of these approaches to creating a hierarchy. Even if a treatment is proven to have efficacy in two independent research studies, for example, the question of its effectiveness in a real-world setting remains.

Furthermore, treatment decisions depend not only on the strength of the methods used to establish efficacy or effectiveness, but also on a weighing of benefits against the risks and costs of treatment (41). Table 3.1.2.6 shows an approach to creating a hierarchy of recommendations about treatments based on combining the methodologic strength of the supporting evidence and the clarity of the balance between risk and benefit for that treatment. At the top of this hierarchy are treatments with excellent evidence for efficacy and/or effectiveness as well as clearly defined benefits

outweighing clearly defined risks and costs. The number summarizes the clarity of the risk/benefit balance and the letter summarizes the likelihood that the supporting evidence is free from bias (or methodologic strength).

SEARCHING THE LITERATURE

General Tips on Searching

The most relevant databases for clinicians are Medline, PsycINFO, the Cochrane Library's Central Register of Controlled Trials (CENTRAL), the JAACAP website, and Google Scholar. A clinician familiar with these four databases and how they work is able to quickly answer many useful questions. Table 3.1.2.7 demonstrates results from searching three of these sites for answers to varied answerable questions. Results are shown as the number of retrieved publications, or "hits." The first search in the table arose treating a 14-year-old boy with Tourette syndrome and ADHD. He was taking desipramine (DMI) after stimulants had greatly worsened his tics and atomoxetine had made him nauseous. When he started DMI his grades improved markedly, and he reported being able to focus. Four years later, he was continuing to do well, but his physician wondered whether there was new information regarding desipramine and sudden death in youth. He quickly found an article raising further concerns (42) and spoke with the family about retrying atomoxetine. The second search regards information on PMT began because a multidisciplinary team was looking for an EST to use with oppositional and defiant youth. The quotation marks around the phrase "parent management training" (PMT) greatly improve the specificity of the search, reducing hits from 299 to only 10 highly relevant ones. The quotation marks specify that these three words must be found as a phrase, rather than appearing individually throughout the title or abstract. The clinician in this case quickly found support for learning it (43).

TABLE 3.1.2.6

GRADING TREATMENTS BASED ON RISK/BENEFIT CLARITY AND STRENGTH OF EVIDENCE

Grade	Clarity of Risks + Costs Versus Benefits	Strength of Evidence
1A	Clear	Multiple RCTs with no important flaws
1B	Clear	One or more RCTs with significant flaws and/or inconsistent results
1C+	Clear	No RCTs for this population, but RCT results can be extrapolated to the present patient *or* overwhelming evidence from observational studies Birth
1C	Clear	Observational studies
2A	Unclear	RCTs without significant limitations

2B	Unclear	RCTs with methodologic flaws and/or inconsistent results
2C	Unclear	Observational studies
Adapted from Guyatt et al. (41).		

Several Tips About Using These Four Databases are Helpful in Searching

1. *For efficiency, consider starting with searches yielding information high in the pyramid of evidence using the "Clinical Queries" feature of PubMed at https://www.ncbi.nlm.nih.gov/pubmed/clinical.* This feature allows you to access the most valid evidence quickly if your question is primarily about the efficacy of a therapy (44). Using the filters for a narrow, specific search is a good starting point in evaluating a therapy since the site will now retrieve only RCTs. If the result is negative, then move on to the "sensitive" search filter that will include nonrandomized studies as well; your search is moving down the pyramid of evidence. On the other hand, if time is not an issue, consider starting with a sensitive search and being as inclusive (sensitive) as possible; only later narrow the search by becoming increasingly narrow (specific).
2. *Consider with starting with low-bias, preappraised evidence form systematic reviews and meta-analyses*. A review qualifies as systematic if it explicitly states its inclusion and exclusion criteria, uses a comprehensive and transparent search strategy as well as explicit rules to summarize the data (45).

   Searching the PubMed Clinical Queries site, for example, with the terms "self-harm (children OR adolescents)" and the "Broad" filter retrieves 305 clinical studies, while the "Narrow" filter reduces that to 75 hits, a more manageable number to "hand search," the term used to briefly examine each abstract and assess its relevance and validity (46).
3. *Be familiar with Medical Subject Headings (MeSH) and how to "explode" or restrict MeSH subheadings, as well as how to use search tools such as Boolean operators and "wildcards."* Asking the search to explode a MeSH term means the program will now look for all subheadings of that MeSH term in addition to the term itself. At times this is useful; at other times, it is more useful to search only one or more specific subheadings of a MeSH term.

   Become familiar with how to use the MeSH "tree" of terms and subheadings, and note that PsycINFO does not use MeSH, but uses its own thesaurus. Become familiar as well with Boolean operators like "and," "or," and "not," which can quickly either expand or limit a search. Wildcards are useful in allowing searching with multiple terms in a single search. "Adolesc*" in Medline will retrieve, for example, articles on adolescence, adolescents, and adolescent. All databases have a tutorial function that explains its wildcards and its thesaurus; these are database specific.
4. *Understand the strengths and weaknesses of each database related to the*

journals it does and does not contain. PubMed retrieves many references for medications but omits many significant journals in psychology. PsycINFO includes an extensive array of psychology journal articles of variable quality; this database has its own thesaurus of index terms as well. The JAACAP Website offers AACAP members full text access to articles published since 1995, but only from a single, albeit highly relevant, journal. The Cochrane Library's Central Register of Controlled Trials is helpful as a complete source for RCT data; its Systematic Reviews library rarely has completed reviews in child psychiatry. Table 3.1.2.7 summarizes characteristics of these databases.

5. *Understand which databases are available and whether each produces an abstract alone or a full text article*. Both Medline via Entrez PubMed at the National Center for Biotechnology Information (NCBI) and the Website of the Journal of the American Academy of Child and Adolescent Psychiatry are available to most child psychiatrists. The former is in the public domain and generates abstracts, while the latter is included in membership in the American Academy of Child and Adolescent Psychiatry. Three other databases often available via an institutional affiliation are the Cochrane Library's Central Register of Controlled Trials (CENTRAL), its database of Systematic Reviews, and the database PsycINFO from the APA. Most clinical "answerable questions" can be usefully searched using a combination of JAACAP, PubMed, CENTRAL, and PsycINFO. But in most organizational affiliations with Ovid, only some journals will supply full text access to the retrieved articles and abstracts. Hence, an advantage in searching the JAACAP site first is its access to full text articles; this avoids the frustration of finding excellent sources but being unable to obtain a full text copy immediately.
6. *Use branching out from a good specific reference whenever possible*. Look in the bibliography and expand from there. Look for other articles by the same author or by authors cited in the bibliography. Also note the MeSH subject term for a reference you find very helpful and use it for a MeSH search. This approach often quickly creates an expanding web of relevant references. One of the best examples of the "one good reference leads to another" strategy is Greenhalgh's review article on disseminating an innovation (20). Note also that databases like PubMed offer searching of "Relevant Articles" as a link.
7. *Search a single aspect of a multi-item search at a time, then combine sets of references using Boolean operators*. For example, in searching Medline for outbreaks of suicide attempts in adolescents, search the MeSH term for suicide attempts separately initially. Search the MeSH term for outbreaks separately as well. Only then combine the sets of references using the Boolean operator "and" to find references in both sets. Finally, add limits such as age, year of publication, language of publication, and publication type serially one at a time. The advantage of this approach is transparency. How many hits were achieved at each stage and the effect of combining sets, as well as the effect of each limit, is clear. This transparency is useful because, if necessary, you can immediately

revise your search based on the results. Dropping references should also be done using a transparent methodology. Justifying each step of winnowing is worthwhile, since each such narrowing step means lost information. "Hand searching" simply means scanning the abstracts or even whole articles and deciding their relevance and quality for the purpose at hand. Hand searching is the final step after winnowing through limits.

8. *Know what to do when the search retrieves far too many references to examine*. In Medline, consider using the subheadings under MeSH terms to refine the search. For example, adding "Major" (abbreviated [MAJR]) after the term restricts the search to only those articles where the subject is a major topic heading in that journal article. Similarly, subheadings to MeSH terms like "prevention and control" or "statistics" can be helpful in limiting large searches if those are areas of primary concern. Using the "Limits" feature in databases also narrows the number of references. Common limits are either specifying a specific publication type, such as only meta-analyses or only RCTs, or only a specific age group such as adolescents, or only the most recent references from perhaps the last 5 or 10 years. Suppose, for example, a reader is interested in doing a comprehensive search on psychodynamic psychotherapy in children. He might start by searching the term "Psychotherapy [MeSH]" which uses the MeSH category psychotherapy, generating over 97,000 references. Limiting to age 6 to 12 reduces the number to about 14,000. Searching Medline with the term "psychodynamic" as a keyword and the limit of age 6 to 12 generates a more manageable 257. Combining these two sets generates a manageable list of 116 references to sort through. This list is a good start.

TABLE 3.1.2.7

"Hits" (Retrieved References) in Selected Databases Accessed via Ovid[a]

Database	Search Terms	Limits	Hits	Comments
PubMed	Desipramine *and* death	Age 0 to 18 Last 5 yrs	4	PubMed is a good place to begin for search terms like desipramine or atomoxetine, that is, for information regarding medications.
	Desipramine *and* "Death, sudden"	Age 0 to 18 No time limits	15	
	Parent Management Training	Age 0 to 18 Last 5 yrs	299	
	"Parent Management Training"	None	20	
Clinical Queries at PubMed ("therapy" box)	"Parent Management Training"	Specific search Sensitive search	4 8	Clinical Queries' specific searches retrieve only randomized trials.
Cochrane Library's CCRCT via Ovid	Parent management training "Parent management training"	None None	7 7	The Cochrane Library databases are more difficult to use than these other Websites; they lack the "limits" options, for example, of other sites

PsycINFO (1985–2004 via Ovid)	"Parent management training"	None	79	PsycINFO is a good place to begin for search terms like "bullying" or "stepfamily problems."
	"Parent management training"	None	79	
Evidence-Based Mental Health Online	Desipramine Desipramine *and* death "Parent management training" "Parent management training"	None	16 1 9 2 2	Many references to child/adolescent literature. Requires subscription to search beyond first 150 words of article.

Tips on PubMed

To use PubMed well, it pays to understand MeSH terms, the National Library of Medicine's controlled vocabulary for medical subject headings. MeSH index words provide a consistent way to retrieve information even though articles may use varied terminology for the same concept. In other words, the MeSH term is the "official" term used by the database to organize all references relevant to a single subject that may be referred to using multiple words. Using MeSH terms in a search ensures that all references relevant to that subject are included. Furthermore, MeSH terms are organized as nested sets, becoming more and more specific; each term higher in the tree contains all the terms below it. Medline allows the searcher to visualize these nested sets of terms and choose the most specific term he can find for the subject of interest. This allows only highly specific articles to be retrieved. MeSH searches also allow the searcher to specify whether he wants articles retrieved if the MeSH term is found anywhere in the article, or whether he wants articles retrieved only if the MeSH term is a major heading in the article.

A therapist interested in alternatives to Dialectical Behavior Therapy (DBT), for example, searched "parasuicidal"—meaning frequent cutting or comparable low lethality self-harm attempts—in the MeSH tree of index terms. MeSH recognizes the term parasuicide, and suggests the term "Self-Injurious Behavior." This official MeSH term is defined as "behavior in which persons hurt or harm themselves without the motive of suicide or of sexual deviation" (47). The MeSH tree then looks like this:

Self-Injurious Behavior (SIB)
- *Self-Mutilation*
- *Suicide*
  - *Suicide, Assisted*

Suicide, Attempted

The therapist might want to search "self-injurious behavior" as a MeSH term (simply put [MeSH] after the term). The therapist might choose not to explode the term (meaning the search also would include all four items nested underneath Self-Injurious Behavior) if the goal is to find alternatives to DBT. The unexploded term will be more specific because it will find articles based on the above definition of SIB only and not include the lower terms. The search Psychotherapy [MeSH] AND "Self-Injurious Behavior [MeSH:NoExp]" limited to the age group of adolescence generates 75 references which can be used as a base to answer the therapist's question. By contrast, a less specific search that allows the search to explode the SIB term and include subheadings retrieves over 792 references—far too many to hand search. In summary, exploding a MeSH term—meaning that all the MeSH terms underneath this item will also be searched—is only desirable if all the subheadings are of potential interest.

Tips on PsycINFO

PsycINFO is a database that includes nearly 2,000 journals as well as some books, book chapters, and dissertations. Operated by the APA, it is especially strong in searching questions related to psychosocial interventions.

A search generates abstracts and not full text articles. PsycINFO uses a thesaurus of index terms, providing a controlled vocabulary to structure the subject matter (20). The thesaurus includes more psychological terms than MeSH. "Pretend play," "Bullying," and "Parental involvement," for example, are legitimate thesaurus terms in PsycINFO. Yet in MeSH, "Bullying" has no suggested search strategy, and "Pretend play" in the MeSH tree returns "Play therapy" and "Play and playthings," a subset of Recreation. The PsycINFO thesaurus is available online.

However, not all searches do best with a thesaurus term. For example, searching the term "parent management training" in Ovid's PsycINFO thesaurus shows Parent Training as an index term which includes PMT. But because this index term also includes many forms of parent training, it retrieves 2,756 hits. A more successful strategy for a clinician seeking information about Patterson's well-known Parent Management Training is the keyword search for the phrase in quotes, "parent management training" (see Table 3.1.2.7). Options regards "limits" are also different than those in PubMed. PsycINFO, rather than offering a premade filter to choose only randomized trials, offers the filter "clinical trial" instead.

The searcher can search by index terms from the thesaurus or by keyword. PsycINFO also lists classification codes—large categories with an accompanying number such as "cognitive therapy" (3311) or "group and family therapy" (3313).

Searching by keywords is uncontrolled in that any search term can be tried.

PsycINFO then searches for those words in the title or abstract. When building combined searches using more than one combination of keywords, classifications, or index terms, build the search one step at a time to maximize transparency of the process. For example, typing in “psychodynamic child psychotherapy” into the thesaurus, the index term is “child psychotherapy.” The term itself generates 3,433 hits. Searching this index term exploded generates 4,732 hits. “Psychodynamic” searched in the Thesaurus returns “psychodynamics” as a thesaurus index term. Exploded, this term generates 8,049 hits.

Now combining this set with the results from exploding “child psychotherapy” with the Boolean “AND” creates a manageable set of 41 references. Another approach is to search “psychodynamic$” with “$” being a wildcard—it can represent any letter or combination of letters—and combine it with the results of exploding the index term “child psychotherapy”: The result is 205 references.

Tips on Google Scholar

Google Scholar is a formidable search engine with the familiar Google logo and format. In 2012, it was estimated to have over 160,000,000 references in it. With its hip, colorful logo and familiar format, easy availability, and simple search box it is understandably popular. It is free, fast, and has an “Advanced” search box allowing for search by author, title, or date. Yet, while relatively stark and colorless, PubMed and PsycINFO have major advantages over Google Scholar in seeking low bias and complete results efficiently. First, PubMed and PsycINFO both have filters which function to narrow the search drastically based on the quality of the evidence using well-defined subject labels—MeSH in PubMed and Thesaurus in PsycINFO—in addition to well-defined classification systems for publication types, such as meta-analysis, review, or RCT. Therefore, it is possible to efficiently winnow results to a manageable number based on both publication type and subject label. No such classification has been done in Google Scholar, often resulting in an unwieldy set of references that is difficult to winnow toward the most valid results. And whereas PubMed and PsycINFO are transparent about their contents, Google Scholar is not. It is reassuring to know the boundaries and content of the ocean in which fishing is conducted. And whereas PubMed Clinical Queries filters retrieve a select group of studies chosen for low-bias design, Google Scholar, with its large size and no classification systems, can easily retrieve an unwieldy set of references that is difficult to winnow. Furthermore, since published meta-analyses typically retrieve their data from PubMed, CENTRAL, and PsycINFO and other bibliographic, defined sites, clinicians using these sites also align their own knowledge management procedures with those of definitive published knowledge.

The Cochrane Library

The Cochrane Central Register of Controlled Trials (CCRCT) is an efficient way to begin a search for those with access, because CCRCT strives to be complete, with over 350,000 registered controlled trials; importantly, it includes only controlled trials. Its advantage over a search for RCTs using the Clinical Queries PubMed site is that CCRCT attempts a search for any randomized trial published anywhere in the world (not just RCTs published in a journal indexed by PubMed). A parent seeking help regarding the usefulness of the Feingold diet could find a quick answer in CCRCT. A quick look for Feingold diet at the PubMed Clinical Query site, set for narrow searches, works equally well, and quickly reveals the same negative 1981 trial found in CCRCT. Moreover, the search options at the Clinical Queries PubMed site are easier to use, including the capacity to limit articles retrieved to only adolescents, for example. For this reason the Clinical Queries site may be more relevant for most clinicians unless no trials have been reported, in which case checking CCRCT may be worthwhile.

Historical Perspective: Archie Cochrane and the Virtual Library Named after Him

In 1972, the British epidemiologist Archie Cochrane wrote an influential book, Effectiveness and Efficiency: Random Reflections on Health Services, in which he pointed out that resources for health care would always be limited. Therefore, he concluded, using evidence from randomized controlled trials is critical, because the information they provide is more reliable than other sources of evidence. In 1979, he continued to advocate for the usefulness not only of RCTs, but also for efforts to summarize such trials in one place. “It is surely a great criticism of our profession,” he wrote, “that we have not organized a critical summary, by specialty or subspecialty, adapted periodically, of all relevant randomized controlled trials.” His remarks and influence were such that an international collaboration, the Oxford Database of Perinatal Trials (ODPT), developed around his way of thinking. The systematic review of randomized trials resulting from this collaboration became a centerpiece of what came to be called “the Cochrane approach”: the structured method of presenting overview data summarizing multiple trials. This approach became a hallmark of the Cochrane Database of Systematic Reviews (CDSR), an online “library” that began in the 1980s with the ODPT. The Cochrane Collaboration was subsequently founded in 1993, 5 years after his death.

The symbol for the Cochrane Collaboration is two Cs facing each other and containing a closed circle with a central vertical line. The vertical line represents the null result, that is, an odds ratio of 1.0. Each horizontal line represents the results of a single randomized controlled trial. The length of the line represents the 95% confidence intervals for the primary outcome variable studied in that trial; the shorter

the line, the more certain the results. Some horizontal lines cross the central vertical line, meaning that the null hypothesis was not refuted within 95% confidence intervals. The horizontal lines that do not cross the central vertical line represent a study inconsistent with the null hypothesis as regards the primary outcome variable at the 95% confidence level. This makes it easy to scan the figure visually to see which studies reached significance and which did not. Furthermore, at the bottom there is a small diamond just to the left of the central vertical line. The diamond summarizes the pooled effect estimate from summing over the results of all the trials within the circle.

The specific horizontal lines and diamond used in the Cochrane Collaboration logo (Figure 3.1.2.1) represent a meta-analysis of randomized trials as regards administering a short, inexpensive course of a corticosteroid to women about to give birth prematurely. The first of these RCTs was reported in 1972. The logo summarizes the evidence that would have been revealed had the available RCTs been reviewed systematically in about 1982; the position of the diamond demonstrates that corticosteroids reduce the risk of babies dying from the complications of immaturity. In fact, more modern estimates are that this treatment reduces the odds of premature infants dying from the complications of immaturity by 30% to 50% (48). But because no systematic review of these trials had been published until 1989, this evidence was not widely disseminated and many premature babies presumably died unnecessarily. Hence, the logo is a rather grim reminder of the high stakes in performing systematic, timely reviews of relevant randomized controlled trials.

THE COCHRANE
COLLABORATION®

FIGURE 3.1.2.1. The Cochrane Collaboration logo. (Used with permission, courtesy of the Cochrane Colloquium.)

Abstracts of Cochrane systemic reviews are available for no charge (see Table 3.1.2.8) but access to the full text of the review usually occurs through affiliation with an institution that subscribes. The systematic reviews are updated regularly as more information becomes available, and in response to comments. The methodology is transparent. The "Library" exists only virtually in cyberspace. This system allows updates to include more recent studies and any criticism and comments (49). Comparisons with reviews in traditional journals have given the edge to the Cochrane Library versions (50). Cochrane systematic reviews are exclusively electronic and frequent review and openness to comments have been designed to take advantage of the electronic form (49).

The Cochrane Library thus developed a way of summarizing healthcare information that was systematic, completely electronic, up to date, open to criticism, and clearly distinguishing between trials based on their quality. The "system" used does not vary from review to review. Therefore once the consumer becomes accustomed to the format, he can quickly understand the results of any systematic

review. Furthermore, the results are transparent, since each study's individual results are also summarized, as is the methodology. Finally, since the entire library is electronic, updating by teams working around the globe becomes feasible in a regular way through sharing the work in cyberspace. The Cochrane library has thus raised the bar for how medical knowledge is organized and disseminated, and been closely associated with the development of EBM.

For answerable questions in child psychiatry, the CCRCT is often useful as a good place to start searching an answerable question. Paradoxically, the Cochrane Library of Systematic Reviews is often not useful to child psychiatrists, because a systematic review has most often not been done on the child psychiatric topic of interest. Searching for reviews on ADHD, for example, retrieves 13 reviews but none specifically devoted to ADHD. Searching for reviews on major depression in adolescents is similarly unfruitful. By contrast, searching the Clinical Query site of NCBI in the Find Systematic Reviews box retrieves 229 references with many devoted exclusively to ADHD and many highly relevant to a practitioner (see Table 3.1.2.8). Nevertheless, the Cochrane Library's emphasis on the importance to practitioners of systematic reviews, published in cyberspace and updated frequently, remains at the heart of EBM.

DIAGNOSTIC PATHS CONSISTENT WITH EBP PRINCIPLES

EBP differs significantly from conventional clinical practice in how it approaches differential diagnosis. Whereas clinicians often use an unstructured interview and their familiarity with the categories of DSM-IV TM, EBP encourages feasible routes to more definitive diagnoses compatible with research studies for that disorder. In other words, EBP supports the importance of test/retest and interrater reliability and the multiple forms of validity (51) in the diagnostic process, while also recognizing the process must be feasible. An EBP approach to diagnosis is not new at all; it is merely trying to make feasible the more rigorous diagnostic approaches used in research for some time. In this way EBP is a useful bridge between the culture of research and the culture of clinical care, striving to help clinicians find rigorous yet practical diagnostic methods. EBP also encourages a thorough yet feasible search in symptom domains other than the presenting problem, since comorbid disorders are common and easily missed (52). Let's begin with how EBM approaches arriving at a clear conclusion in the domain of a primary diagnostic concern and return to the issue of assessing comorbid disorders.

In diagnostic work, the EBM practitioner should try to create a link between his patient's disorders and the research base on effective treatments. It is important, therefore, that the diagnostic procedures are not idiosyncratic to that practitioner or clinic. The diagnostic system used must also generate data capable of becoming

useful information when compiled. The EBS youth mental health clinics in Hawaii, for example, establish an initial baseline of functioning using the CAFAS (28). When the CAFAS is repeated 3 months later, its mean and median slope are useful measures of changes in functioning in the population served by these clinics (8).

The clinician may at times elect to use a component of a research-level instrument, especially in the domain of primary concern. For example, the K-SADS-P/L modules for selected diagnoses such as MDD, bipolar, bulimia nervosa, alcohol abuse, and multiple other disorders can be given as "stand-alone" modules within the context of a clinical interview as a compromise. Of course administration of the complete K-SADS provides a more thorough evaluation. This semistructured approach with clear anchor points to determine the presence or absence of symptoms is markedly less ambiguous than simply working from an open copy of DSM-IV. Furthermore, K-SADS modules are available free on the Internet (53). Another feasible research-level instrument is the computerized Diagnostic Interview Schedule for Children (DISC), which can be administered only for the domain of interest or in multiple domains in a wide search for psychopathology (54).

Another approach is to use an instrument which has been studied as a proxy for a research-level instrument, and been shown to be a feasible substitute. For example, in pediatric bipolar disorder (PBD), the parent version of the Young Mania Rating Scale (P-YMRS) has been studied as a proxy for a semistructured interview (55). Higher scores on the P-YMRS predict increasing likelihood of PBD on semistructured interviews. In order to use these likelihood ratios, it is necessary to estimate the base rate of BPD among patients presenting to the clinic (56). Such a base rate can either be estimated using published data or from local data generated at the clinic itself. The latter process is recommended only if the diagnostic process used locally has been adequate. Using data from the literature to calculate a base rate for common disorders like ADHD, MDD, bipolar disorder, and substance abuse disorders has advantages: the sample sizes are larger, and use peer-reviewed data typically generated with well-defined diagnostic processes.

Bayes' theorem can be used to combine the information from an estimated base rate, family history, and parent-completed instrument assessing bipolar symptoms. Consider the example of a 9-year-old patient with episodes of extreme aggression, problems concentrating, and high levels of motor activity (56). To begin, the base rate for bipolar disorder in children entering community mental health center clinics is roughly 6%; this figure, therefore, becomes the initial estimated probability of bipolar disorder. Since this boy had a biologic father with bipolar I and a meta-analysis showed that children with a biologic parent with bipolar disorder are five times as likely to have a bipolar diagnosis themselves, Bayes' theorem allows the clinician to combine these two independent sources of information as follows (57):

Initial estimate of odds of bipolar disorder = Odds of having bipolar disorder in clinic × likelihood ratio from family history

Note that Bayes' theorem uses the odds, rather than the probability, of the boy having bipolar disorder. The information given as regards a base rate of 6% is actually a probability, which would need to be converted to odds for use in Bayes' theorem. A nomogram uses probabilities and avoids the clumsiness of converting probabilities to odds for use in Bayes' theorem and then back again to probability, the more familiar concept (see Figure 3.1.2.2). The nomogram shows that this boy's probability rises to 24% from 6% on the basis of his positive family history.

Bayes' theorem allows the clinician to further refine the probability of this boy's meeting diagnostic criteria for bipolar disorder by using his mother's reports of his symptoms as reported on the externalizing score on the Child Behavior Check List. This process is especially helpful in ruling out bipolar disorder, that is, showing that the probability of the boy meeting criteria for bipolar disorder is sufficiently low that no further testing is required. On the other hand, a high externalizing score on the CBCL should trigger use of a specific parent report regarding bipolar symptoms, such as the Parent Young Mania Rating Scale (P-YMRS). In such a case, continue to use Bayes' theorem with the boy in the example (58):

Refined odds of bipolar disorder = (Odds for probability of 24) × (likelihood ratio from that patient's score on P-YMRS)

Again, using a nomogram that translates probability into odds and back again to probability after the calculation makes things easier. With a likelihood ratio of 6 from his P-YMRS score, this boy's probability of having bipolar disorder jumps to 68.

This is not a diagnosis, but it is an easily arrived at probability which should trigger a full-scale evaluation for bipolar disorder (see Youngstrom's discussion [59]). This methodology can be used to estimate the probability for other disorders such as ADHD as well (56).
FIGURE 3.1.2.2. Nomogram for combining probability and likelihood ratio. (From Youngstrom EA, Youngstrom JK: Evidence-based assessment of pediatric bipolar disorder, Part II: incorporating information from behavior checklists. *J Am Acad Child Adolesc*

Psychiatry 44:823–828, 2005, with permission.)

In addition to feasible but empirically supported approaches to a primary diagnosis, data support using a broad assessment of psychopathology and functioning. There are many possible instruments. Achenbach's multiple-informant System of Empirically Based Assessment (ASEBA) is one feasible approach, as is a computerized structured interview such as the parent and child versions of the DISC (54). Broad-based structured systems like ASEBA and the DISC are more likely to note comorbid anxiety disorders, substance abuse disorders, and the presence of multiple disorders than an unstructured clinical interview (59).

In comparing DISC diagnoses to diagnoses generated by clinicians in unstructured interviews, for example, agreement was higher for externalizing than for internalizing disorders, and clinicians were more likely than the DISC to assign a single diagnosis and less likely to assign no diagnosis. Systems like the ASEBA and DISC avoid the heuristic biases present in an unstructured diagnostic interview and their results are useful in building a local database. Such systems allow the interviewer more time and energy to pursue individual aspects of that child's psychosocial functioning and the context of his symptoms—favorite Internet sites and bands, friendships with peers, relationships with parents and teachers, idealized heroes and heroines, and cell phone ring tone (60). In other words, broad-based, structured assessments can complement a clinical interview. The goal is to provide both a technically sound measure of psychopathology and function as well as a youth-friendly, youth-relevant experience.

In summary, there is no single diagnostic process consistent with EBP; there are many. The goals include a complete, wide-ranging assessment of functioning, impairment, and psychopathology that is unlikely to miss disorders with significant morbidity. The approach also ideally uses feasible methods to provide a solid empirical link to major studies in the field, as well as a baseline for tracking outcome and generating local data. Sound yet practical diagnostic and/or tracking tools useful in everyday practice are noted in Table 3.1.2.9; each is either in the public domain or reasonably priced.

ENACTING EVIDENCE-INFORMED CARE IN CLINICAL ORGANIZATIONS

The task of moving an organization from its current practices toward functioning with processes more consistent with EBP has been called implementation. But projects designed to do this have taken much longer than originally intended (11), creating an implementation gap. More recently, some have suggested the term enactment of evidence-informed health care as a replacement for the term implementation (11). The term enactment comes from enactment theory, which focuses on subjective issues in how organizations function rather than on formal organizational charts. A clinical team is, therefore, enacted by individuals based on their own social perceptions of a negotiated order based on repeated interpersonal processes (68).

Leading a multiprofessional organization toward EBP is complex, with many disputes about the meaning of the change. Furthermore, the available evidence in favor of any particular innovation is often ambiguous; it is inevitably open to at least some interpretation and will be contested. Varied professional groups each have their own way of thinking about what constitutes evidence and its meaning, leading inevitably to competing claims on the truth. Each professional group has its own paradigms and cognitive assumptions, leading to each advancing different claims to knowledge (69). As a result, it is often difficult to find common ground for productive dialogue. Instead, each discipline proceeds almost on its own path, resulting in a complex situation which actually allows the end-user clinician increased choice among the competing claims (11). In addition, managerial control over elite professional groups is limited, since autonomy over working practices is a core value for elite professionals (11).

Creating change in a multiprofessional healthcare organization is complex for several other reasons as well. First, the context of change efforts to enact EBP varies enormously from one organization to another, and varies over time even within the

same organization (70). What external pressure is there on the organization to survive in a competitive market? How do union-management issues and interprofessional "turf" issues shape the organization? How does its history shape its culture? This series of questions is only a start. In other words, no context is discrete; complex connections and interactions are the rule. Assessing outcome is also complex. Basic issues as when change is assessed and what is measured can change results markedly. Also, large healthcare organizations respond not only to multiple professional groups inside the organization, but to accrediting bodies and government agencies outside its boundaries. Consider, for example, the complexity of disputes about the safety and benefits of selective serotonin reuptake inhibitors in depressed youth. Government agencies, the press, national professional organizations, and research evidence were all involved.

Tips on Enacting Evidence-Informed Health Care in Organizations

A review of six studies designed to implement EBP for varied medical conditions came to several conclusions. First, implementing change is facilitated by open access to membership in key groups that filter the literature and create guidelines and educational initiatives (8,71). In Hawaii's successful efforts to develop an EBS for youth mental health, groups of clinicians, administrators, and community members involved in the project had open membership; anyone willing to do the reading and attend regularly was allowed to join (4). Second, the hierarchical structure of the local team or hospital staff influences adoption of EBP; a more "flat" hierarchy offers less resistance to adoption. In a vertical hierarchy, junior staff members defer to more senior members regardless of the evidence, slowing adoption of EBP. Third, networks of social/professional relationships, rather than individuals, are central in whatever actions result from implementation efforts. Individuals live within and are a part of these networks.

From these studies, several useful guidelines appear for those interested in implementing EBP within the context of their own organization:

1. *An evidence-based perspective becomes reality only when it is enacted in local clinical settings by frontline clinicians*. Adopting a formal policy of committing to EBPs is insufficient by itself to create enactment by frontline clinical groups over which senior management has limited control (11).
2. *Think of context not as a stage for the action of change, but rather as an active element in the change process*. A shift toward EBP—like other organizational change processes—is highly context dependent (11), where context is defined as multidimensional, multifaceted configurations of forces, often developing historically as negotiated interpersonal patterns. Because these forces interact in complex ways, unexpected outcomes from a planned change

are common (10). Individuals are influenced by the context of a network of social relationships beyond their immediate circle. Hence no context is discrete or separate.

3. *Key leaders are able to influence innovation toward EBP*. Although it is clear that the process is often complex, a senior, powerful, and skillful leader can stimulate innovation (10).
4. *Take into account the distinctive nature of the multiprofessional organization*. Boundaries—educational, cognitive, and social—between different professional groups inhibit the spread of EB ideas. Child psychiatrists may read only child psychiatry journals and not child psychology journals and vice versa, or attend only their own professional organizational meetings and vice versa. Knowledge can be powerful and threaten specific interest groups, which are then motivated to reject it (10).
5. *Use the extensive literature on "exporting" psychosocial interventions from development sites to practice sites and distilling components of effective treatments*. How to train practitioners to use manualized therapies developed at other sites is a topic that has been widely discussed elsewhere (71,72). Another approach is to use a process of distilling the common elements in evidence-based interventions and then match these with profiles of target symptoms from individual clients (73). This latter approach is novel and has great potential.
6. *Use multiple means to motivate practitioners to adopt EB processes*. A project to disseminate synthesized evidence to pediatric clinicians concluded that multiple routes of evidence are necessary to convince practitioners to apply evidence in daily patient care (74). An organization is more able to tip toward applying evidence to direct patient care when the organization recognizes a local problem in how it uses research results, and differentiates among classes of evidence. Data showing results from the state of Hawaii's efforts to implement EBP makes a compelling case for the value research can add to practice; it also illustrates how Hawaii's clinicians differentiate among classes of evidence (30). Established means of influencing practitioners' behaviors, such as "best practice" groups, are also useful means to convey EBP ideas (74). Building on such natural social groups is more likely to result in behavioral change in practitioners than efforts to impose major changes in a top-down approach (68).
7. *Because context is complex and multiple routes are necessary to persuade practitioners to change, enacting evidence-based approaches in child mental health needs to be uniquely tailored for each organization and each desired change*. Summaries of how organizations change to include new practitioner behavior more grounded in evidence suggest multiple processes or activities are necessary to create change (20,75). In brief, activities known to promote change successfully include skill-based training, evaluation of therapist fidelity and of programs, practice-based coaching, a facilitative administration, a well-defined implementation team, a high level of facilitator involvement, clarity in defining

the core components being implemented, hiring practices, and organizational readiness. The latter is defined by a clear need for change, funding, the confidence of the implementation team, and the involvement of stakeholders (20).

Enacting Evidence-Informed Health Care: An Outpatient Team, an Individual Practitioner

Despite the conclusions that certain drivers of change within healthcare organizations are effective, there is no single way to implement EBP because context is all-important. For example, an opinion leader physician at an outpatient child psychiatry team chose to initiate and support context-sensitive efforts to improve the functioning and quality of life in a larger proportion of the youth served, to make these improvements more substantial, and to make them occur more quickly. Aware that organizational change processes like a shift to EBP are highly context dependent, she first made an effort to understand the team's context (76). One key aspect, she realized, was the multidisciplinary nature of the team—psychologists, physicians, and social workers. Such diverse professional groups do not share a universal, communal, and disinterested approach to knowledge; rather, each discipline displays distinct cognitive assumptions, often with clear boundaries around the discipline's knowledge, making knowledge often difficult to transfer from one discipline to another (77). Not only may the paradigms for generating knowledge in each profession be different, they may be so different that they lack common ground for productive dialogue. Each professional group may therefore produce bodies of knowledge that are not seen as authoritative within other groups (11).

She solved this by creating a work group open to anyone on the team willing to attend meetings and do the work required to complete the project. The group's first task would be to create a plan for how the team would approach youth with anxiety disorders. She led the group toward reviewing the work of the principal leaders in this field but also reviewing all published RCTs studying youth with panic disorder, generalized anxiety disorder, social anxiety disorder, separation anxiety disorder, or a phobia. Using the PubMed Clinical Queries site and limiting the search to recent publications focused on children or adolescents, she found a workable number of references for each disorder, and the group began its work. The work group's goal was to put together a short list of those core components appearing frequently in the most effective treatments. The group then chose those core components that both appeared frequently in effective treatments and were also feasible to use in the context of their setting, characterized by high volume and limited therapist availability. The work group stayed in touch via email and at team meetings with those staff members not participating in the literature review and feasibility discussions. The core components chosen as feasible within that context and

supported by more than 1 RCT were exposure, relaxation training, cognitive restructuring, and fluoxetine. The approach she used—distillation of the literature into core components, and subsequently matching those components to a specific client in treatment—was well accepted by therapists. It helped that the process used was inclusive, open, and transparent; it may also have helped that the process respected therapists' autonomy and expertise in matching components and specific patients (73). The work group is currently developing ways to monitor fidelity to these core components.

Just as in organizations, there is no single path to implementing EBP among practitioners. Studies have shown that EBP is best learned in small group teaching experiences. Yet some practitioners may be able to improve their practice simply by being inquisitive, searching for evidence regards the answerable question as originally developed by EBM teachers (3). Resolving to improve his method of tracking response to treatment, for example, one practitioner began tracking symptoms in adolescents with anxiety disorders using an available instrument he uncovered through a Medline search (78). Similarly, he found that tracking responses of attention deficit/hyperactivity youth to stimulant treatment was inexpensive and feasible using an available brief report instrument (61) similar to the instrument used in the MTA study (79). This allowed him to build an alliance with parents by discussing likely outcomes. Parents appreciated the more thoughtful follow-up and their appreciation reinforced his change in behavior.

Solo practitioners can also benefit from joining the organization that uses their combined results to answer research questions, the Child and Adolescent Psychiatry Trials Network (79), allowing them to participate in research studies and inevitably piquing curiosity. In general, changing even an individual's practice begins with an action—a commitment to do something differently, be it a diagnostic process, a treatment decision, or choosing a follow-up methodology. Published summaries of EBP processes in child and adolescent psychiatry may be useful in reflecting on a starting point that is a good fit for a specific practitioner (80).

Errors, Child Psychiatry, and EBP

Error can be defined as "the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim" (81). Like other physicians, child psychiatrists undoubtedly make errors. Yet in 2017 the search term "pediatrics" in PubMed and "medical errors" retrieves nearly 400 publications in the last 10 years whereas substituting the term "child psychiatry" for "pediatrics," only 7. Child psychiatrists may be less concerned than pediatricians about medical errors because our procedures do not include surgery, ICU care, chemotherapy, and similar invasive procedures, but also because our most frequent errors go unnoticed.

Developing a culture that is both rigorous *and* kind *and* searches for its own

errors while focusing on systemic processes needing improvement is an important task in building and maintaining child mental health systems (82). EBP can help because it offers a metric for the effect of an error, the quality-adjusted life year. The QALY includes both any change in survival time for the patient as well as any change in the patient's quality of life and the duration of that change (83).

Errors of omission are undoubtedly common: An adolescent who has PTSD resulting from having been physically abused who receives only supportive treatment, or an oppositional child with ADHD who is treated with play therapy alone or treating an adolescent suffering from anorexia with supportive psychotherapy when more specific and proven treatments are available (84,85). Perhaps the most frequent error of omission is delay in treatment due to access problems or waiting lists. Delay increases the odds of diminished quality life years compared to anticipated outcomes from treatment.

In addition to making errors of omission, child psychiatrists can, of course, also make errors directly causing harm. Diagnostic errors during assessment can result in a drop in outcome results (86). Polypharmacy treatment with two or more antipsychotics may proceed with limited evidence of safety and efficacy (87), and excessive hospitalization in some states in the past have damaged youth with unnecessary stigma (88). With many possibilities both for errors of omission and errors in assessment and treatment, it makes sense for child mental health systems to build error detection into the core of their organizations. Vigorous error-detection systems can make a difference, such as a second opinion regards medications for outliers, fidelity monitoring, supervision, training, and specific technologies to support interventions (88,89).

CONCLUSION

Contemporary child psychiatry requires a practice model realistic enough to recognize the vast array of contexts in which evaluations and treatments are delivered, yet rigorous enough to insist that each youth receive the most proven diagnostic process and treatment feasible in that setting. Clearly this is vastly different from each clinicians relying on personal preference—it is more time consuming and more difficult than practice as usual. Results from the Hawaii group suggest it can make a substantial change in the bottom line of youth outcome, however, making the effort well worthwhile.

CHAPTER 3.1.3 ■ RESPECT FOR CHILDREN AS RESEARCH SUBJECTS

ROBERT J. LEVINE

"So act as to treat humanity, whether in thine own person or in that of any other, in every case as an end withal, never as a means only." The German philosopher Immanuel Kant, writing late in the eighteenth century, provided this formal statement of the ethical principle of respect for persons. Persons are to be regarded as ultimate values in and of themselves; they are not to be used merely as means to another's goals.

Those who conduct research involving human subjects first define their goals and then identify persons whom they use as means to accomplish these goals. This is not unethical. What is proscribed is the use of persons merely as means—"as means only." To avoid this, researchers are required both ethically and legally to secure the approval of persons to be used as research subjects through a process called informed consent. If this approval entails acceptance of the researcher's goals, then the subject is not used merely as a means. Rather, the subject freely chooses to embrace the goals as his or her own and thus remains an end.

This chapter is concerned with informed consent and other issues related to the principle of respect for persons (e.g., privacy and confidentiality) as they relate to the involvement as research subjects of adolescents and children of various ages.

ETHICAL PRINCIPLES

The basic ethical principles identified by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research (1) as those that should underlie the conduct of research involving human subjects are "respect for persons," "beneficence," and "justice." These principles were endorsed subsequently by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (2) as "basic values" for medical practice as well as for biomedical and behavioral research, calling them by somewhat different names: "respect," "well-being," and "equity." According to these authoritative commissions, research involving human subjects should be conducted in accord with norms or rules designed to uphold and embody these basic principles or values. These rules are assembled in federal regulations for the "protection of human research subjects"; most relevant to the present concerns are those of the Department of Health and Human Services (Code of Federal Regulations, Title 45, Part 46; hereafter abbreviated as 45 CFR 46)[1] and the Food and Drug Administration (FDA) (Code of Federal Regulations, Title 21, Parts 50 and 56; hereafter abbreviated as 21 CFR 50 and 21 CFR 56).

In this chapter there are frequent references to federal regulations. This is not intended to suggest that all ethical considerations are reflected adequately in the law. Rather, the regulations in this field generally represent a broad social consensus about what ought and ought not to be done. Even for research not covered by the regulations, they have come to be regarded as establishing a community standard, departures from which require justification (3). The regulations include both substantive and procedural rules (norms). A substantive rule specifies behaviors that are required (or forbidden) because they are morally right (or wrong). Some procedural rules specify procedures that should be performed to determine the most appropriate behavior when the behavior has not been specified by a substantive rule. Other procedural rules are designed either to assist in the adherence to the requirements of a substantive rule or to provide documentary evidence that research has been conducted in accord with the relevant substantive rules (3).

AN ILLUSTRATION

The principle of respect for persons requires that human persons must be treated as autonomous agents. The substantive norm that requires informed consent is a specification of one way in which this principle is to be made operational in the conduct of research involving human subjects. The procedural norm that requires review and approval by an institutional review board affords a method for determining what specific bits of information must be divulged to prospective subjects in a particular research protocol. Another procedural norm that requires the signing of a consent form provides documentary evidence that the behavior required by the substantive norm has been accomplished. The form itself assists the investigator's efforts to comply with the substantive rule.

> ***According to the National Commission:***
> Respect for persons incorporates at least two basic ethical convictions: First, that individuals should be treated as autonomous agents, and second, that persons with diminished autonomy and thus in need of protection are entitled to such protections. An autonomous person is … an individual capable of deliberation about personal goals and of acting under the direction of such deliberation (1).

To show respect for autonomous persons requires that we leave them alone, even to the point of allowing them to choose activities that might be harmful (e.g., hang gliding), unless they agree or consent that we may do otherwise. We are not to touch them or encroach on their private spaces unless such touching or encroachment is in accord with their wishes. Our actions should be designed to affirm their authority and enhance their capacity to be self-determining; we are not to obstruct their actions unless they are clearly detrimental to others. We show disrespect for autonomous

persons when we either repudiate their considered judgments or deny them the freedom to act on those judgments in the absence of compelling reasons to do so.

Clearly, not every human being is capable of self-determination. The capacity for self-determination matures during a person's life; some lose this capacity partially or completely, owing to illness or mental disability or in situations that severely restrict liberty, such as prisons. Respect for the immature or incapacitated may require one to offer protection to them as they mature or while they are incapacitated.

Because the central focus of this chapter is on respect for persons, it is necessary to emphasize that the other two principles are of equal importance in the sense that they have equal moral force. Research involving human subjects can be considered ethically justified if, and only if, it is adequately responsive to each of the three basic ethical principles (3). As we shall see, considerations of justice and beneficence place constraints on, for example, whom we can ask to serve as research subjects and how much risk we may ask them to accept in the interests of research.

INFORMED CONSENT

Principle I of the Nuremberg Code (4) provides the definition of consent from which definitions supplied in all subsequent codes and regulations are derived:

> The *voluntary* consent of the human subject is absolutely essential.
>
> This means that the person involved should have *legal capacity* to give consent; should be so situated as to be able to exercise *free power of choice,* without the intervention of any element of force, fraud, deceit, duress, over-reaching or other ulterior form of constraint or coercion; and should have sufficient *knowledge* and *comprehension* of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision [emphasis added].

Thus, consent is recognized as valid if it has each of these four essential attributes: It must be competent (legally), voluntary, informed, and comprehending (or understanding).

It is through informed consent that the investigator and subject enter into a relationship, defining mutual expectations and their limits. This relationship differs from ordinary commercial transactions in which each party is responsible for informing himself or herself of the terms and implications of any of their agreements. Professionals who intervene in the lives of others are held to higher standards. They are obligated to inform the layperson of the consequences of their mutual agreements.

It is worth noticing that the Nuremberg Code defines and requires "voluntary consent." Since 1957 this term has been replaced by "informed consent," a term that reflects an idealized vision of the person as a rational, self-determining agent (5).

Federal regulations identify "elements" of information that must be transmitted

during the negotiations for informed consent (45 CFR 46.116a); these are:

1. A statement that the study involves research, an explanation of the purposes of the research, and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures that are experimental
2. A description of any reasonably foreseeable risks or discomforts to the subject
3. A description of any benefits to the subject or others that may reasonably be expected from the research
4. A disclosure of appropriate alternative procedures or courses of treatment, if any, which might be advantageous to the subject
5. A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained
6. For research involving more than minimal risk, an explanation as to whether any compensation and an explanation as to whether any medical treatments are available if injury occurs and, if so, what they may consist of or where further information may be obtained
7. An explanation of whom to contact for answers to pertinent questions about the research and research subjects' rights, and whom to contact in the event of a research-related injury to the subject
8. A statement that participation is voluntary, refusal to participate will involve no penalty or loss of benefits to which the subject is otherwise entitled, and the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled

In addition, according to the regulations, the following elements must be provided "when appropriate" (45 CFR 46.116b):

1. A statement that the particular treatment or procedure may involve risks to the subject (or to the embryo or fetus, if the subject is or may become pregnant) that are currently unforeseeable
2. Anticipated circumstances under which the subject's participation may be terminated by the investigator without regard to the subject's consent
3. Any additional costs to the subject that may result from participation in research
4. The consequences of a subject's decision to withdraw from the research and procedures for orderly termination of participation by the subject
5. A statement that significant new findings developed during the course of the research that may relate to the subject's willingness to continue participation will be provided to the subject
6. The approximate number of subjects involved in the study

The regulations define only minimum standards for informed consent. In most cases it seems appropriate to supplement these basic requirements with additional elements of information (3). For example, prospective subjects should be told why they have been selected as invitees to participate in the research; ordinarily, this

consists of a statement of the major inclusion and exclusion criteria for the protocol. In addition to the statement of "additional costs to the subject" required by the regulations, there should also be accurate statements of any cash payments or other economic advantages associated with participation in the research as a subject.

How does one determine whether any particular fact (e.g., any particular risk of injury) must be disclosed? The legal criterion for disclosure in the context of medical practice is "material risk," that is, any fact that is material to the patient's decision must be disclosed (3,6). The determination of which risks are material in that they must be disclosed may be accomplished according to three different standards or tests (3,7). Until recently, the prevailing standard was that of the "reasonable physician"; the determination of whether any particular risk or other fact should be disclosed was made on the basis of whether it was customary to do so in the community of practicing physicians.

The standard that is now applied most commonly is the "reasonable person" or "prudent patient" test. In the case of *Canterbury* v. *Spence* (8), the court held that the disclosure required was determined by the patient's right of self-decision, a right that can be effectively exercised only if the patient possesses enough information to enable an intelligent choice. A risk is thus material when a reasonable person, in what the physician knows or should know to be the patient's position, would be likely to attach significance to the risks or cluster of risks in deciding whether or not to forego the proposed therapy.

Some courts have adopted the rule that a risk is material if the particular patient making the choice or decision considers it material. Of the three standards, this rule, which some call the idiosyncratic person standard, is most responsive to the requirements of the ethical principle of respect for persons. It is, however, a highly impractical standard.

In the author's view, the reasonable person standard should determine the minimum amount of information that should be imparted by the researcher to each and every prospective subject. Then, in the course of the consent discussions, the researcher should attempt to learn from each prospective subject what more he or she would like to know.

Federal regulations permit "a consent procedure which does not include, or which alters, some or all of the elements of informed consent" or, in some cases, waiver of the entire requirement for informed consent, if:

> [a] The research involves no more than minimal risk to the subjects, [b] The waiver or alteration will not adversely affect the rights and welfare of the subjects, [c] The research could not practicably be carried out without the waiver or alteration, and [d] Whenever appropriate, the subjects will be provided with additional pertinent information after participation (45 CFR 46.116d).

Implicit in these conditions—particularly the second condition—is recognition of the standard of materiality. One may not withhold any material information without adversely affecting the rights of subjects. Waivers and alterations are commonly used in research involving medical records, “leftover” specimens of tissues and body fluids from which personal identifying information has been removed, survey research, and so on. It is more problematic when researchers propose to alter information for purposes of deceiving prospective research subjects (3).

The Department of Health and Human Services (DHHS) makes it clear that, “Nothing in these regulations is intended to limit the authority of a physician to provide emergency medical care, to the extent the physician is permitted to do so under applicable federal, state, or local law” (45 CFR 46.116f). Implicit in this rule is a recognition of two exceptions to the legal requirement for informed consent: the emergency exception and therapeutic privilege.[2]

The FDA permits waiver of the consent requirement for the use of investigational new drugs (or other regulated test articles) in the treatment of individuals in “life-threatening situations” in which “informed consent cannot be obtained … because of an inability to communicate with, or obtain legally effective consent from, the subject” (21 CFR 50.23). There is also a provision in FDA regulations for an exception from informed consent requirements for emergency research; this exception is designed for research activities in which most or all of the prospective subject population will be unable to consent and it will not be feasible (usually owing to lack of time) to get consent from a legally authorized representative (21 CFR 50.24).[3]

CONSENT FORMS

Thus far we have been considering informed consent, a process designed to show respect for subjects, fostering their interests by empowering them to pursue and protect their own interests. The consent form, by contrast, is an instrument designed to protect the interests of researchers and their institutions by defending them against civil or criminal liability. I believe that one of the reasons there has been so little successful litigation against investigators, as compared with practicing physicians, is the very formal and thorough documentation of informed consent on consent forms. Consent forms may be detrimental to the subject’s interests not only in adversarial proceedings; signed consent forms in institutional records may lead to violations of privacy and confidentiality (3).

> DHHS regulations require:
> A written consent document that embodies the elements of informed consent…. This form may be read to the subject or the subject’s legally authorized representative, but, in any event, the investigator shall give either the subject or the representative adequate opportunity to read it before it is signed (45 CFR

46.117).[4]

Although the primary purpose of the consent form is to protect the interests of researchers and their institutions, it is forbidden by federal regulations to:

> include any exculpatory language through which the subject or the representative is made to waive or appear to waive any of the subject's legal rights, or releases or appears to release the investigator, the sponsor, the institution or its agents from liability for negligence.[5]

DHHS requires that "[a] copy shall be given to the person signing the form" (45 CFR 46.117). The primary purpose of the form notwithstanding, it can and should be designed to be helpful to the subjects. Having a copy of the form will afford them an opportunity to continue to get more information as additional questions occur to them. It can also serve as a reminder of the plans they must follow in order to accomplish the purposes of research, of the symptoms they should watch for to protect their own safety, of the perils of omitting doses of drugs, and so on. It can serve as a guide to conversations they might choose to have with family, friends, personal doctors, and other trusted advisors about whether they should consent; in some cases such conversations should be recommended during the consent negotiations. In the use of these forms, however, the researcher should heed the words of the President's Commission (10): "Ethically valid consent is a process of shared decision-making based upon mutual respect and participation, not a ritual to be equated with reciting the contents of a form that details the risks of particular treatments."

No consent form can be designed so as to anticipate all of any particular prospective subject's wishes to be informed. The consent form is most effective when it is viewed by the researcher as a guide to the negotiations with the prospective subject. The consent form should contain at least the minimum amount of information and advice that should be presented during the negotiations. If any substantive new understandings are developed in the process of negotiations that have any bearing on the prospective subject's willingness to participate, these should be added to the consent form signed by that individual.

DHHS regulations (45 CFR 46.117) permit waiver of the requirement for documentation of informed consent if:

1. The only record linking the subject and the research would be the consent document and the principal risk would be potential harm resulting from a breach of confidentiality.
2. The research presents no more than minimal risk of harm to subjects and involves no procedures for which written consent is normally required outside of the research context.

In some cases in which the regulations permit waiver of the requirements for

documentation, it may be advisable to provide subjects with information sheets. These documents provide a written account of all information that could serve subjects' interests in ways suggested earlier. They differ from consent forms primarily in that they are not signed by subjects and retained by researchers. Thus, they afford limited protection to the researcher and the institution.

JUSTIFICATION OF RESEARCH INVOLVING CHILDREN

Children, as a class of persons, lack the legal capacity to consent. Moreover, many of them, particularly the younger ones, are not only incapable of sufficient comprehension to meet the Nuremberg Code's standard but are also not "so situated as to be able to exercise free power of choice." It is necessary to rely on other devices to show respect for children because they cannot consent. Two of these devices are permission and assent.

Permission of one or both parents or of the legal guardian is closely related to what was formerly called proxy consent. With few exceptions, federal regulators regard permission as a necessary condition for authorizing the involvement of a child as a research subject; for children who cannot assent, it is usually a sufficient condition as well. The transactions involved in negotiating a valid permission are in all respects identical to those of informed consent.

Assent by the child should be as close an approximation of consent as the child's capabilities permit.

Before proceeding with our discussion of permission and assent, it is necessary to return to a consideration of the basic ethical principles.

Respect for persons requires that we treat individuals as autonomous agents only to the extent that they are autonomous. As noted earlier, "[p]ersons with diminished autonomy and thus in need of protection are entitled to such protections (1)." In response to this ethical conviction, there is established in federal regulations a standard called "minimal risk," which "means that the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests" (45 CFR 46).[6] Minimal risk serves as a threshold standard in that plans to involve children in research that presents more than minimal risk require special justification and procedural protections.

But many therapeutic procedures present far more than minimal risk, and it is not customary to obstruct children's access to them by calling for special procedural protections. The regulations make it clear that the minimal risk standard is applicable only to procedures that do not "hold out the prospect of direct benefit for the individual subjects" (45 CFR 46.405). Therapeutic procedures, by contrast, are to be authorized and justified precisely as they are in the practice of medicine. That is to say, the risk of any procedure is justified in terms of the benefit expected for the

individual child-subject who will bear that risk. Also, as in medical practice, the relationship of anticipated benefit to the risk presented by the procedure must be at least as advantageous to the subject as that presented by any available alternative, unless, of course, the subject (or his or her parents) has considered and refused to accept a superior alternative. These rules are responsive to the ethical principle of beneficence, which as articulated by the National Commission (1) is expressed in the form of two general rules: "(1) Do no harm; and (2) maximize possible benefits and minimize possible harms."

Justice, as envisioned by the National Commission, requires a fair sharing of the burdens and benefits of society (1,3). In the distribution of these burdens and benefits, special consideration is to be given to those who are vulnerable or disadvantaged. Children are considered vulnerable and are to be protected from exploitation because they lack the capacity to consent. They are not to be involved in research that is irrelevant to the class of person of which they are representative. When appropriate, research should be done first on adults and then on older children before involving younger children and infants (3).

In summary, children and their parents are not completely free to do their own thing. There are constraints grounded in ethical considerations and enforced by regulations regarding whom researchers may invite to serve as subjects and how much risk they may be asked to assume for research purposes. With these constraints in mind, we now turn to further consideration of assent and permission.

ASSENT

Respect for children does not require that we leave them alone even to the point of allowing them to choose dangerous activities unless they agree that we may do otherwise. Young children have no such liberty rights. What they have instead is a right to custody (12). We show respect for them by fostering their well-being, protecting them from harm, and guiding them to become "the right kind of people."

As we have already noticed, federal regulations reflect the obligation to protect children from harm and to secure their well-being. Let us now consider the obligation to guide their moral and social development—an obligation not recognized explicitly in the regulations.

In the 1970s there was a spirited debate over the legitimacy of using persons who are incapable of consent ("unconsenting subjects") as research subjects. Paul Ramsey (13) argued that it is always morally wrong. Richard McCormick (14), arguing the opposing viewpoint, pointed out that members of a moral community have certain obligations. One of these is to contribute to the general welfare when to do so requires little or no sacrifice. In the case of children, one may presume that they would consent if they could; he calls this a "correctly construed consent." In his view, when supplemented with parental permission, correctly construed consent

authorized the use of children as subjects in research that fulfilled an important social need and involved "no discernible risk."

At this point, Terrence Ackerman (15) entered the debate, arguing that we tend to fool ourselves with procedures designed to show respect for the child's very limited autonomy. He claims that the child tends to follow "the course of action that is recommended overtly or covertly by the adults who are responsible for the child's well-being." He further contends that, in general, this is as it ought to be. "Once we recognize our duty to guide the child and his inclination to be guided the task becomes that of guiding him in ways which will involve his well-being and contribute to his becoming the right kind of person."

Willard Gaylin (16) tells the story of a man who acted in accord with Ackerman's position. After directing his 10-year-old son to cooperate with a venipuncture for research purposes, he explained that his direction arose from his perceived moral obligation to teach his child that there are certain things one does to serve the interests of others even if it does cause a bit of pain:

> This is my child. I was less concerned with the research involved than with the kind of boy I was raising. I'll be damned if I was going to allow my child, because of some idiotic concept of children's rights, to assume that he was entitled to be a selfish, narcissistic little bastard.

Parenthetically, while it is appropriate to guide and persuade a 10-year-old boy to submit to a venipuncture for research purposes, it is not ethically defensible to command him to do so against his will; it is also contrary to the requirements of federal regulations. Guiding children to become the "right kind of persons" entails teaching them about and encouraging them to embrace the sense of obligation to the moral community discussed before. It further entails showing respect for their maturing capacities for self-determination; one hopes the child will learn to choose to do unto others as the child would wish them to do unto her or him.

At what age does a child become capable of assent? Federal regulations specify no age, leaving it to the discretion of the Institutional Review Board (IRB), taking into account not only the age but also the maturity and psychological state of the children involved.

As the assent regulation is written, it seems to reflect a presumption that the capability to assent is an all-or-none phenomenon; the child is either capable or incapable of assent. This presumption is incorrect (17,18) and, the author believes, unintended by the regulation writers. In the author's view the regulations are intended to be interpreted to permit a determination that prospective child-subjects may be capable of understanding some but not all of the elements of informed consent. Thus, for example, it may be appropriate to provide some children with "a description of any reasonably foreseeable risks or discomforts," without providing "an explanation

as to whether any compensation [is] available if injury occurs."

It is possible to make some general comments on the capabilities to assent of children having normal cognitive development in various age groups. According to Lois Weithorn (17), who relates her empirical findings to Piaget's concepts of cognitive development:

> … in general, developmental research suggests that most school-aged children are capable of meaningful assent for participation in most types of research studies. This means that the children probably are capable of comprehending the nature of the proposed procedures, the general purpose of the research, and of expressing a preference regarding participation. Research suggests that normal children ages 6 and older are quite capable of thoughtful and reasoned consideration of the types of information that investigators may provide.

Typically, at about age 11, children's cognitive development enters the "stage of formal operations," during which they become increasingly sophisticated in their capacities to reason about "possibility" and other abstract concepts. From ages 7 to 11, in the "stage of concrete operations," the child is more or less limited to thinking about matters that are not too far removed from concrete reality. Thus, there are those who argue that the "age of assent" should be around 6 or 7, and others who say it should be around 11 or 12.[7]

Weithorn (17) continues:

> Early empirical findings also suggest that, although they may not be legally authorized to provide independent consent for treatment or research in most jurisdictions, normal adolescents age 14 and older may be as capable as adults of making competent decisions about such participation, according to the more stringent legal standards of competency.

The authority of mature and emancipated minors to consent is discussed subsequently in this chapter.

PERMISSION

Parental permission is envisioned by the National Commission as a reflection of the collective judgment of the family that an infant or child may participate in research (3,19). In most cases the permission of one parent is sufficient; one may assume that he or she will represent the family's wishes satisfactorily.

When more than minimal risk is presented by a nontherapeutic procedure, the permission of both parents is required unless one is "deceased, unknown, incompetent, or not reasonably available, or when only one person has legal

responsibility for the care or custody of the child" (45 CFR 46.408).

There are three additional criteria for justification of nontherapeutic procedures that present more than minimal risk (45 CFR 46.406): First, the degree of risk is limited to "a minor increase over minimal risk." Second, the procedure or intervention must be "likely to yield generalizable knowledge which is of vital importance for the understanding or amelioration of the subject's disorder or condition."[8] Third, the procedure or intervention must present "experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations." This means that the procedures must be ones that they or others with the specific disorder or condition under study will ordinarily experience by virtue of their having or being treated for that disorder or condition. Thus, it might be appropriate to invite a child with leukemia who has had several bone marrow examinations to consider having another one for research purposes.

The requirement of commensurability reflects the National Commission's judgment that children who have had a procedure performed on them might be more capable than are those who are not so experienced of basing their assent on some familiarity with the procedure and its attendant discomforts; thus their decision to participate will be more knowledgeable.

Even though the parent gives permission, the child's refusal to assent to nontherapeutic interventions should be respected. Those who are incapable of assent may have some capacity to make their wishes known. The term *deliberate objection* is used to recognize that some children who are incapable of meaningful assent are able to communicate their disapproval or refusal of a proposed procedure. A 4 year old may protest, "No, I don't want to be stuck with a needle." However, an infant who might in certain circumstances cry or withdraw in response to almost any stimulus is not regarded as capable of deliberate objection. A child's deliberate objection usually should be regarded as a veto to his or her involvement in research (3,19).

In the case of therapeutic interventions or procedures, the situation is much different. Federal regulations state simply, the assent of children is not a necessary condition (45 CFR 46.408). Parents have both the right and responsibility to override the objection of school-age children to necessary therapy. With regard to teenagers, decisions regarding authorization of investigational therapies are about as complicated as they are in the practice of medicine. The law recognizes the authority of emancipated and some mature minors to consent to or refuse standard or accepted therapy; these rules are not recognized explicitly in federal regulations regarding investigational therapies.

In the practical world of decision making about who can authorize a therapeutic procedure, whether it is investigational or accepted, it rarely suffices to point to the law and thereby identify the person who has the legal right to make the decision.

Many factors must be taken into account in reaching judgments about the capability of various persons to participate in and, in the event of irreconcilable disputes, prevail in such choices. In general, these judgments become more complicated as the child gets older or the stakes get higher (16,20).

IRBs have the authority to waive the requirement for permission when "it is not a reasonable requirement … provided an appropriate mechanism for protecting the children is substituted" (45 CFR 46.408). The regulations suggest as an example of research in which a requirement for parental permission might not be reasonable is that on "neglected or abused children." The National Commission (19) specified several other examples:

> Research designed to identify factors related to the incidence or treatment of certain conditions in adolescents for which, in certain jurisdictions, they may legally receive treatment without parental consent; research in which the subjects are "mature minors" and the procedures involved entail essentially no more than minimal risk that such individuals might reasonably assume on their own; research designed to meet the needs of children designated by their parents as "in need of supervision," and research involving children whose parents are legally or functionally incompetent.

THE NATIONAL COMMISSION (19) FURTHER ELABORATES:

> There is no single mechanism that can be substituted for parental permission in every instance. In some cases the consent of mature minors should be sufficient. In other cases court approval may be required. The mechanism involved will vary with the research and the age, status and condition of the prospective subject ….
>
> Assent of … mature minors should be considered sufficient with respect to research about conditions for which they have the legal authority to consent on their own to treatment. An appropriate mechanism for protecting such subjects might be to require that a clinic nurse or physician, unrelated to the research, explain the nature and the purpose of the research … emphasizing that participation is unrelated to provision of care. Another alternative might be to appoint a social worker, pediatric nurse, or physician to act as surrogate parent when the research is designed, for example, to study neglected or battered children. Such surrogate parents would be expected to participate not only in the process of soliciting the children's cooperation but also in the conduct of the research, in order to provide reassurance for the subject and to intervene or support their desires to withdraw if participation becomes too stressful.

The recommendations of the National Commission reflected their assumption that the "normal" family is one in which the members stand in a loving relationship to one

another and that the parents in such a family will strive to protect the interests and welfare of their children. This point notwithstanding, they were aware of the fact that there are exceptions. In obvious cases (e.g., neglected or abused children) they recommended that the IRB should have the authority to waive the requirement for parental permission. In the less obvious cases, of which there may be many, decisions as to whether the parents are loyal to their children and welfare require sophisticated professional judgment. The National Commission wisely refrained from recommending that IRBs engage in micromanagement of such cases. Implicitly, the responsibility for such judgments is assigned to the investigator. The National Commission provided a margin of safety by recommending special substantive and procedural protections in cases in which more than minimal risk is presented by interventions that do not hold out the prospect of direct benefit for the individual child-subject.

In recent years there has been increasing interest in giving mature minors independent authority to authorize their own participation in certain types of research without requiring permission of their parents or guardians. To some extent this interest reflects a general trend in public policy toward facilitating inclusion as research subjects members of groups who were previously excluded (21). This interest also represents a pragmatic response to problems presented by the AIDS pandemic; specifically, many, and perhaps most, adolescents will not enroll as research subjects if this necessarily entails allowing their parents or guardians to learn or even suspect certain details of their sexual or drug-taking experience (22).

Most of the current federal regulations for the protection of human subjects reflect the attitude that prevailed in the 1960s and 1970s when they were written, that investigational drugs and participation in research were dangerous and researchers were likely to exploit subjects. Since the mid-1980s, primarily as a consequence of the efforts of AIDS activists, this vision has been largely replaced by one that research participation and access to investigational drugs are both more beneficial than burdensome. As a result of this shift in perception, public policies that were designed to protect persons from harm and exploitation, particularly those persons who are considered vulnerable by reason of limitation in their capacity to give informed consent, are being reinterpreted or rewritten to assure the same classes of persons equitable access to the benefits of investigational drugs as well as to the benefits of participation in research (21).

It has long been known that restrictive policies on involvement of children in research have resulted in a class injustice. Children as a class have been deprived of the benefits of the new knowledge that could result from carrying out research involving children as subjects. This deprivation is exemplified by the fact that approximately 80% of the drugs approved by the FDA for commercial distribution are not labeled for use in children, usually because sufficient studies have not been conducted in children (23,24). In recent years agencies of the federal government

have begun to respond to this class injustice. The National Institutes of Health now require that applications for grants or contracts to conduct research involving human subjects must include plans to enroll children unless the applicant can justify their exclusion (25). Similarly, the FDA requires inclusion of children in research done to support an application for a marketing permit unless the sponsor can justify their exclusion (26,27).

At the time of this writing, federal policies have not been revised to permit involvement of mature minors as research subjects on their own authority except as discussed earlier in this chapter. However, it seems reasonable to predict that in the near future there could be such changes in the relevant policies or their interpretation. Santelli et al. (28) and Levine (29) have published examples of specific proposals. Inclusion of children who are wards (e.g., of the state) in research in which more than minimal risk is presented by nontherapeutic interventions requires special procedural protections that are beyond the scope of this discussion (45 CFR 46.409) (3). Many states and cities have regulations designed to protect the interests of foster children.

Concern has been expressed recently that such regulations often create formidable bureaucratic barriers to involving such children in randomized clinical trials or gaining them access to investigational drugs. For two reasons this presents a special problem to children with AIDS: (a) A large percentage of such children are foster children; and (b) many apparently effective therapies for AIDS and its complications are investigational drugs (30).

DOCUMENTATION

The regulatory requirement for documentation of permission is exactly the same as it is for informed consent. In circumstances in which there is no requirement for permission because the minor is authorized to assent for himself or herself the same requirements for documentation obtain. Apart from this, when children are asked to sign forms, as they often and quite properly are, the principal purpose, in the author's view, is to enhance their sense of participation in the process.

PRIVACY AND CONFIDENTIALITY

Privacy is "the freedom of the individual to pick and choose for himself the time and circumstances under which, and most importantly, the extent to which, his attitudes, beliefs, behavior, and opinions are to be shared with or withheld from others" (31). Because this is the definition used in this chapter, some matters considered by the law to fall under the rubric of privacy are excluded (the right to abortion and contraception). In general, in clinical research, intrusions into individuals' privacy

are permitted only with their informed consent. There is no invasion when an informed person allows a researcher into his or her private space.

Confidentiality is a term that is all too often used interchangeably with *privacy*. Confidentiality refers to a mode of management of private information; if a subject shares private information with (confides in) a researcher, the researcher is expected to refrain from sharing this information with others without either the subject's authorization or some other justification.

The ethical grounding for the requirement to respect the privacy of persons may be found in the principle of respect for persons. The ethical justification for confidentiality, according to Sissela Bok (32), is grounded in four premises, three of which support confidentiality in general; the fourth supports professional confidentiality in particular.

First and foremost, we must respect the individual's autonomy regarding personal information. To the extent they wish, and to the extent they are capable of doing so, they are entitled to have secrets. This facilitates their ability to live according to their own life plans.

Closely related is the second premise, which recognizes the legitimacy not only of having personal secrets but also of sharing them with whomever one chooses. This premise, which embodies an obligation to show respect for relationships among human beings and respect for intimacy, is exemplified by the marital privilege upheld in American law, according to which one spouse cannot be forced to testify against the other.

The third premise draws on the general requirement to keep promises. A pledge of confidentiality creates an obligation beyond the respect owing to persons and existing relationships. Once we are bound by a promise, we may no longer be fully impartial in our dealings with the promise.

These three premises, taken together, provide strong prima facie reasons to support confidentiality. That is to say, they are binding on those who have accepted information in confidence unless there are sufficiently powerful reasons to do otherwise—as, for example, when maintaining confidentiality would cause serious harm to innocent third parties.

Bok's fourth premise adds strength to the pledge of silence given by professionals. The professional's duty to maintain confidentiality goes beyond ordinary loyalty, "because of its utility to persons and to society … Individuals benefit from such confidentiality because it allows them to seek help they might otherwise fear to ask for" from doctors or others who can provide it.

Investigators, of course, are not necessarily professionals to whom individuals turn for professional help. Thus, only part of the fourth premise applies to investigators, the part that grounds the justification and requirement for confidentiality in its social utility. If researchers violated the confidence of their subjects, subjects would refuse to cooperate with them. This, in turn, would make it

difficult, if not impossible, for researchers to contribute to the development of generalizable knowledge.

Over the millennia, the professions have viewed the obligation to maintain confidentiality as very important. The Hippocratic Oath requires, “What I may see or hear in the course of the treatment or even outside the treatment in regard to the life of men, which on no account one must spread abroad, I will keep to myself holding such things shameful to be spoken about.”

Thomas Percival’s *Code of Medical Ethics* (33), on which was based the first code of ethics of the American Medical Association, incorporated the following exhortation: “Patients should be interrogated concerning their complaints in a tone of voice which cannot be overheard.”

In all states, the law not only recognizes the obligation of physicians and many other professionals to maintain confidentiality, it requires it. In many states, there are statutes granting testimonial privilege to information secured by physicians from patients in the course of medical practice (34). Testimonial privilege means that physicians cannot be compelled to disclose such information even under subpoena. Although the United States Supreme Court refused to extend the constitutional protections of privacy to physician–patient communications, the *Federal Rules of Evidence,* promulgated by the Judicial Conference, defer to state law on physician–patient privilege (34).

Most state laws on physician–patient privilege contain various exceptions, including mandatory reporting of information regarding battered and abused children, various communicable diseases, gunshot wounds, and certain proceedings concerned with health issues, including workers’ compensation and insurance claims (34).

In 1974, in the case of *Tarasoff* v. *Board of Regents,* the supreme court of California ruled that a psychiatrist has a duty to protect the intended victim of a patient’s threat of violence, if it is likely that such a threat would be carried out (35); this often but not always entails a duty to warn the intended victim. Subsequently, this duty has been recognized in many other states. The same principle is often invoked in debates over whether state laws should be changed to either permit or require doctors to warn sexual partners of persons infected with the HIV virus if they are unwilling to do so themselves (36).

It must be recognized that the right to confidentiality or privilege belongs to the patient. The patient may authorize sharing of private information for whatever purposes he or she chooses. In civil or criminal litigation where the patient makes the information in his or her medical record material to the support of his or her position, as so often happens in child custody cases or malpractice litigation, the court usually requires that the contents of the record be disclosed (35).

CONFIDENTIALITY IN RESEARCH

Most direct social injuries to research subjects result from breaches of confidentiality. An investigator may identify a subject as a drug or alcohol abuser, as a participant in various deviant sexual practices, as having any of a variety of diseases that may be deemed unacceptable by his or her family or social or political group, as having a higher or lower income than acquaintances might have predicted, as a felon, and so on. If certain individuals know such information, it might cost the subject his or her reputation, job, social standing, credit, or citizenship.

In recognition of these threats of social injury, federal regulations require the IRB to determine that "Where appropriate, there are adequate provisions to protect the privacy of subjects and to maintain the confidentiality of data" (45 CFR 46.111a).

How does one determine that provisions to maintain confidentiality are "adequate"? The first step is to become aware of the variety of factors that may pose threats to confidentiality in the research context. The second is to become aware of the various devices that are available to secure the confidentiality of research data.

The National Commission (37) offered some suggestions for safeguards of confidentiality: Depending on the degree of sensitivity of the data, appropriate methods may include coding or removal of individual identifiers as soon as possible, limitation of access to data, or the use of locked file cabinets. Researchers occasionally collect data that, if disclosed, would put subjects in legal jeopardy. Because research records are subject to subpoena, the National Commission suggests that when the identity of subjects who have committed crimes is to be recorded, the study should be conducted under assurances of confidentiality that are available from DHHS as well as the Department of Justice. For detailed information on these assurances of confidentiality, which provide immunity from subpoena, see (38).

CONSENT

As mentioned in the preceding, informed consent regulations require "a statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained." Statements about confidentiality of research records should not promise more than the researchers can guarantee. For most studies in which the private information to be collected is not especially sensitive, it suffices to state that the researchers intend to maintain confidentiality, that they will take precautions against violations, and that all reports of the research will be in the form of aggregated data and devoid of identifiers. When dealing with more sensitive information, it may be useful to specify some of the precautions; for example, videotapes will be destroyed within 60 days or, if the subject so requests, earlier; data will be kept in locked files; individuals will be identified by a code and only a small number of researchers will have access to the key that links code numbers to identifiers.

Plans to incorporate data in the subject's medical record should be made explicit.

In general, when these data are relevant to patient management, they should be incorporated unless the subject objects. Incorporation of the results of nonvalidated diagnostic tests may lead to false diagnostic inferences, with adverse consequences to the patient's medical care or insurability. Most people do not understand the full implications of signing forms that release their medical records to insurance companies (39).

It is essential to disclose all serious threats of confidentiality breaches that can be anticipated. One such disclosure was used in a study of devices designed to encourage young children who are thought to have been abused sexually to speak freely of their experiences. A portion of the permission form for the normal control subjects reads as follows (3):

> Because this study is not intended to be related to either diagnosis or therapy for you or your child, you are entitled to decide whether the information obtained during this study should be entered into the medical record. If, however, during your child's interview, his or her behavior raises a concern of sexual abuse, a clinical evaluation of your child will be performed…. If after that evaluation the suspicion of sexual abuse persists, the case will be reported as mandated by law.

FDA regulations require (21 CFR 50.25a) "a statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained and notes the possibility that the [FDA] may inspect the records."

As noted earlier, federal regulations permit waiver of the informed consent requirement under certain conditions. These conditions are usually but not invariably met in studies of medical records (given adequate safeguards of confidentiality) or of "leftover" specimens obtained at autopsy, surgery, or collection for diagnostic purposes of body fluids such as blood or urine. In general, use of tissues or fluids without consent is justified if two conditions are satisfied (3): (a) No more tissue or fluid is removed than the amount needed to accomplish the medically indicated purpose of removal; and (b) the specimens are obtained by the researcher under conditions of anonymity (the diagnostic laboratory removes all personal identifiers before giving the specimens to the researcher).[9]

The practices just described are invasions of privacy. In such cases, patients are said to have a right of notice, that is, a right to be notified that such practices occur in the institution. These notices, which partially mitigate the invasion, are commonly printed in patient information brochures and on permission forms for surgery or autopsy. Although they are designed to afford patients opportunities to object, objections are rare. For examples of such notices, see Levine (3).

In some cases, with suitable justification, even the right of notice may be waived. Examples of such activities include collections of cord blood from neonates under conditions of anonymity in a nationwide study to determine the prevalence of HIV

antibodies (3); monitoring for compliance in some randomized clinical trials (3); and covert observation or recording of public behavior (3). Further discussion of these activities and their justification is beyond the scope of this chapter. It must be noted that covert observation is a mild form of deception. In some cases even stronger forms of deception may be justified (3,40).

Researchers commonly use medical or laboratory records to identify patients who might be suitable subjects for their studies. Having identified them, they then contact them by telephone or mail with invitations to participate in research. Those who are contacted usually do not recall having read notices describing such activities in hospital brochures. Some will wonder why a stranger who knows his or her diagnosis is calling. Careful plans must be made to avoid offending patients in such activities (3).

CHILDREN AND PRIVACY

The concerns of young children about privacy are different from those of older children and adolescents (41). Young children first develop territorial privacy ("This is my room") and possessional privacy ("This is my tricycle") and only later begin to develop informational privacy (concerns about others' knowledge of one's activities, associations, and interests). Thus young children may not know that what they say to others may be detrimental to the privacy interests of their families.

DHHS regulations are responsive to this concern. There are several classes of research that are generally considered so free of complicated ethical problems that they are exempted from coverage by the regulations (45 CFR 46.101b). Two of these exemptions do not apply to research involving children: (a) research involving survey or interview procedures; and (b) research involving observation of public behavior in which the researcher is a participant. These activities are not exempt in cases in which they "could reasonably place the subject at risk of criminal or civil liability or be damaging to the subject's financial standing or employability."

Researchers often must secure the approval of various custodians of children to involve them in research. Such custodians may be teachers, daycare workers, camp counselors, and the like. At times it is important to withhold or disguise some of the purposes of the research in order to protect the family's privacy or to avoid prejudicial treatment of children. For example, one would generally avoid telling teachers that the children are selected because they are offspring of parents with emotional disturbances.

As mentioned, informed consent requires "an explanation of the purpose of research." Does this mean that parents must always receive a full disclosure of purposes? Suppose the purpose is—as it was in one study—to determine whether little boys with XYY chromosome patterns are more likely than those with XY patterns to develop violent behavior. Disclosure of such a purpose could become a

self-fulfilling prophecy. For further discussion of withholding the purpose of research and its justification, see Levine (3).

As mentioned earlier, the requirement for parental permission may be waived in "research designed to identify factors related to the incidence or treatment of certain conditions in adolescents for which … they may legally receive treatment without parental consent." In general, the types of activities contemplated by this rule are treatment of sexually transmitted diseases, provision of contraceptive advice, and other matters that teenagers consider highly sensitive. We recognize the teenager's right to privacy, but how far should we go to protect it? Some of the factors that require consideration are illustrated in the following exchange.

Herceg-Baron (42) published a case study in which she detailed some of the special problems involved in research in the field of family planning involving minors as subjects. Many adolescents wish to seek advice about such matters as contraception without the awareness of such others as their parents. She details her institution's policy for protecting the minors' confidentiality. For instance, with regard to follow-up, investigators are required to offer various options, for example, telephone calls during certain hours when the minor knows she will be at home alone; contacts through school personnel such as nurses, teachers, or counselors; contacts by mail containing no agency letterhead or other identifying information; or leaving messages with friends.

In commenting on this case study, Carol Levine (43) raises several concerns. First, she suggests that many adolescents are ambivalent about clandestine sex and would, with some encouragement, welcome open discussion with their parents. The great concern with privacy seems to undermine the possibility for what could be valuable communication within the family. Levine is further concerned about the fact that the institution not only approves deception, but also it collaborates with the adolescent in deceiving her parents. This, she argues, sets a very poor example for the adolescent.

This brings us back to a point discussed in the preceding. Parents are not the only adults having responsibility for guiding the child to become the "right kind of person." Professionals must be aware of the fact that children see them as models of proper behavior. Consciously or otherwise, they provide examples that children will emulate. Accordingly, they should be especially careful not to suggest by example that promises (e.g., of confidentiality), truthfulness, and other ethical matters discussed in this chapter are to be taken lightly. In short, they should help children understand the importance of showing respect for persons.

ACKNOWLEDGMENTS

---

[1]SubPart A of 45 CFR 46, the basic DHHS regulations for the protection of human subjects are customarily referred to as the Common Rule because, with minor variations, they have been endorsed and adopted by almost all of the federal departments that conduct or support research involving human subjects. The other parts of the regulations providing special protections for fetuses and pregnant women (SubPart B), prisoners (SubPart C), and children (SubPart D) have not been adopted as part of the Common Rule. To avoid confusion in this chapter all

DHHS regulations are referred to as 45 CFR 46. At the time of this writing, the DHHS Secretary's Advisory Committee on Human Research Protections is reviewing SubPart D with the aim of clarifying their definitions and the concepts. Their website is revised from time to time to show the current state of their deliberations (www.hhs.gov/ohrp/sachrp/index.html).

[2]For an authoritative commentary on these two exceptions, see Appendix 1 of the President's Commission's Report, Making Health Care Decisions (2). For a more concise discussion see Levine (3).

[3]There are further conditions specified by FDA in its regulations. For further discussion of 21 CFR 50.23, see Levine (3). For 21 CFR 50.24 see Brody (9).

[4]The Department of Health and Human Services regulations also permit use of a "short" form. Use of this form of documentation seems even more complicated and cumbersome than use of the standard consent form. Moreover, its use requires a witness to the consent discussion (3).

[5]Such language is also forbidden in the consent discussion (CFR 46.116).

[6]The term *minimal risk* presents many problems. As it is defined, it may be interpreted in several different ways. For a discussion of its deficiencies, see Levine (3) and Kopelman (11). For an excellent discussion relating the concept of risk to the child's level of development, see Thompson (41).

[7]According to the National Commission (19), a child with normal cognitive development becomes capable of meaningful assent at about the age of 7 years, although some may be younger and some older. The Department of Health and Human Services (DHHS) did not accept this recommendation. Rather, at the time the proposed regulations were published, DHHS solicited public comment on which of three options it should adopt for nontherapeutic procedures: either age 7, age 12, or leaving the age to the discretion of the IRB. The final regulations reflect the third of these options.

[8]What constitutes "minor increase" and "vital importance" is not defined in the regulations. Responsibility for deciding such matters in relation to particular research proposals is assigned to the IRB. If the IRB cannot decide or if it does decide that the degree of risk is more than a minor increase over minimal risk, it must refer the judgment to the Secretary of The Department of Health and Human Services (3).

[9]In some cases it may be impossible to remove identifiers, as when the patient's physician is also the researcher. In such cases the requirement for consent may be waived if the research will not yield any information having diagnostic significance. For further discussion of this point, see Levine (3).

3.2 EPIDEMIOLOGY

CHAPTER 3.2.1 ■ EPIDEMIOLOGY

ERIC FOMBONNE

This chapter introduces the reader to basic concepts and terminology used in epidemiologic research. In the first part, we illustrate how epidemiologists measure disease occurrence, design studies, and select samples to identify risk factors, and evaluate data to establish the causal nature of statistical relationships. In the second part, some achievements of 40 years of epidemiologic research in child psychiatry are reviewed briefly. We first review issues specific to psychiatric epidemiology as they apply to the definition and assessment of child psychopathology in relation to the differentiation between normal and abnormal development, the use of dimensional or categorical approaches to case definition, the need to use impairment measures and to combine data from multiple informants, the need to take into account high rates of comorbidity between disorders, and the implications of pervasiveness or situational specificity of behaviors in estimating rates and risk associations for psychiatric disorders. Basic principles of measurement (reliability and validity) are defined as well as techniques used to screen and evaluate the performance of instruments. We then summarize findings on global psychiatric morbidity in children and adolescents as estimated from recent major population surveys and discuss issues relevant to special groups or new methodologies.

GENERAL EPIDEMIOLOGY

Definition and Historical Background

Epidemiology is the study of the distribution of diseases in human populations and of the factors that influence that distribution. The focus of epidemiology is to study patterns of disease occurrence in order to identify factors that are causally associated with the *onset* of disease in some individuals. Epidemiology relies essentially on *observational* (nonexperimental) methods. *Descriptive* epidemiology is mostly concerned with estimating rates of the disease for public health, or for administrative or monitoring purposes. *Analytical* or causative epidemiology concentrates on the identification of causes of disease occurrence in humans. *Clinical* epidemiology encompasses activities that use epidemiologic methods to study other aspects of a disease, such as its natural history, factors that facilitate offset or persistence of the disorder, or relapse or other outcomes (i.e., mortality). One part of clinical epidemiology employs *experimental* methods (randomized clinical trials), where investigators can manipulate (through randomization) variables (treatments to which patients will be exposed) in designs that facilitate the derivation of causal inferences. Other types of epidemiology (genetic, occupational, psychiatric, etc.) are defined

both by the substantive area of research and by appropriate modifications of epidemiologic techniques and tools, although epidemiologic concepts and theories remain essentially the same across domains of application. The rest of the chapter is concerned with observational studies.

Epidemiology started in the nineteenth century with studies of infectious diseases, such as with the discovery of the infectious nature and mode of transmission of cholera in a London epidemic. In psychiatry, early efforts at the turn of the twentieth century helped to uncover the carential nature of the pellagra encephalopathy; or ecologic studies of suicide led to hypotheses linking suicide rates and social change. After World War II, major epidemiologic studies contributed to the understanding of the risk for cardiovascular disease or demonstrated the causal association between smoking and lung cancer. Explaining this relatively recent development, epidemiologic studies require the collection of large amount of data that may be difficult and costly to acquire. In the last 30 years, epidemiology has developed as an independent discipline, with its own set of concepts and approaches. Medical and biologic knowledge and statistical techniques are used by epidemiologists but epidemiology goes much beyond the statistical analysis of medical data.

Measures of Disease Occurrence

Several measures of disease occurrence are used by epidemiologists. We define here the three most commonly used: incidence rate, cumulative incidence or incidence proportion, and prevalence.

Incidence Rate and Cumulative Incidence

To calculate incidence, individuals initially free of the disease must be observed over a period of time. The example in Figure 3.2.1.1 illustrate new onsets of disease (or death, or relapse, or any other health event) among six individuals observed during a period of 10 units of time (i.e., months or years). Some individuals (subject 1) are observed for the whole observation period, whereas others (individuals 4 to 6) have reduced observation times as they join or leave the sample during the observation period. Three disease onsets (individuals 2, 3, and 5) are observed; for these individuals, the period of observation ceases when the event has occurred, as subsequently they are no longer at risk of developing the disease and the observation time following the event becomes uninformative. The length of the line for each individual in Figure 3.2.1.1 represents the *person-time* experience of this individual and its own contribution to the denominator of the incidence rate. Only events occurring in individuals who are contributing to the person-time denominator are counted.

Incidence : practical example

$$\text{Incidence rate} = \frac{0+1+1+0+1+0}{10+7+2+6+3+8} = 3\,/\,36\,/\,\text{time unit}$$
FIGURE 3.2.1.1. Calculating incidence.

$$IR = \frac{\text{N of new onsets of disease}}{\text{Sum of observation time across individuals}}$$

In the Figure 3.2.1.1 example, the incidence is IR = 3/36 = 0.083 time units^{-1}. IR can vary from 0 to infinite. It has the inverse of time as a unit (i.e., 0.083 per year) which, under some circumstances, can be interpreted as an average waiting time before disease onset. With a fixed number of events, the incidence increases if the person-time denominator decreases, as when the onset of new cases of disease occurs more rapidly, reflecting a faster penetration of the disease in the population. Calculation of incidence rates are more complex in real circumstances, depending on particular assumptions that hold true for the observed population (open [in steady state] or closed population, migration in or out, consideration of competing risks). Common examples of incidence rates are mortality rates, which have an easy intuitive meaning. For example, a young male suicide rate of 20/100,000/year or 0.0002/year means that, if one were to follow up 100,000 young males for a duration of 1 year each, 20 suicidal events would have been occurring during that observation period. However, the same incidence rate could be obtained with four suicidal deaths observed in following 2,000 subjects over a 10-year period. The numerical value of an incidence rate can therefore have different meanings depending on the study methodology.

Because incidence rates are not always that easy to interpret, epidemiologists use other measures of disease occurrence such as cumulative incidence (or incidence proportion). This measure is generally used for a closed population observed over a fixed period of time, all subjects being free of the disease at the beginning of the

observation period. For example, if 9 of 100 siblings of autistic probands develop autism from birth (the beginning of the observation period) to age 3, the cumulative incidence of autism in this high-risk sample would be reported as 0.09 or 9% *over the first 3 years* of life. Unlike incidence rate, this figure is a proportion, dimensionless, and varying from 0 to 1. To be interpreted correctly, this cumulative incidence *must* be reported in conjunction to the length of the observation period, as the cumulative incidence will vary as a function of the follow-up time. In the previous example, if the sample is followed further from age 3 to 5, another six cases might be newly diagnosed with autism, leading to a cumulative incidence of 0.15 *over 5 years* of observation. The intuitive interpretation of cumulative incidence is that it represents the average risk of developing the disease in the population under study (i.e., the summation of individual risks across individuals from the study population). One variant of incidence proportion is survival proportion, which is the complement of incidence proportion (survival vs. death, no recurrence vs. recurrence) and is often used in clinical epidemiologic studies.

Prevalence

Prevalence focuses on disease *status* of individuals within a population rather than on the pattern of *onset* of new cases in that population. Prevalence is not a dynamic measure and, contrary to incidence rate or proportion, no passage of time is required for its calculation. Prevalence is calculated as the proportion of individuals in a population who, at a given point in time, have the disease. Prevalence (P) is a proportion[1] that is dimensionless and varies from 0 to 1. It is calculated as:

$$P = \frac{\text{N of subjects with the disease}}{\text{Population/sample size}}$$

Prevalence incorporates in its numerator recent and past onsets of the disease, and therefore the duration of the disease will influence the prevalence. If the disease is rapidly lethal or if it can be cured rapidly, the number of diseased individuals at any time point will drop and so will the prevalence. Thus, a prevalence rate reflects not only the incidence of the disease but factors that are associated with other aspects of the disease process (availability of treatments, natural history, lethality, etc.). The relationship of prevalence to incidence can be estimated, under some circumstances, as:

$$\frac{Nc}{N - Nc} \approx P \approx I \times D$$

where D is the average duration of the disease, I the incidence, Nc the number of cases in the population, N the population size, and P the prevalence proportion. If the

prevalence is small enough (i.e., <0.10), the formula simplifies to: $P = I \times D$. As I and D have respectively time^{-1} and time as units, P is dimensionless; it is a proportion that varies from 0 to 1. Prevalence rates can be useful as descriptors of the morbidity due to specific causes. They are useful for planning health and educational services. In some circumstances, they may also help generate hypotheses about causal factors associated with disease onset.

In psychiatry, prevalence rates are often referred to specific time periods. For example, a subject who has experienced a major depressive episode during the last 12 months but has now remitted might still contribute to the numerator of a prevalence rate if prevalence in that study is defined as 12-month *period prevalence.* In this example, any individual who met criteria for depression at any time point during the 12 months preceding the survey date would be defined as a case that would contribute to the prevalence pool (the numerator). The most commonly used period prevalence rates are 3-, 6-, and 12-month prevalence rates. Prevalence rates for longer periods of time can be useful to capture events that are either rare or episodic. Because the onset of symptoms of psychiatric disorder is often difficult to determine, psychiatric epidemiologists have often used the concept of *lifetime* prevalence. Thus, any individual who would have experienced a major depressive episode at any point during his lifespan would be counted at the numerator of a lifetime prevalence rate estimate, irrespective of his current disease status, of the age of first onset, and of the total number of depressive episodes experienced by this individual over his lifespan.

Study Designs

The goal of epidemiologic studies is to examine whether or not particular variables are associated with a variation in disease occurrence. These variables are commonly referred to as exposures, as in the example of prenatal exposure to alcohol increasing the risk of neurodevelopmental and behavioral abnormalities in children. Exposures can be susceptibility genes, prenatal or later life exposure to biologic factors, a positive family history, psychosocial stressors, cognitive style or capacity, specific life events, and so on. When exposure to a variable of interest is associated with a demonstrated variation in the risk of the disorder, this variable is referred to as a risk factor for that disorder. A risk factor is statistically associated with the disorder, but this relationship may or not be causal. The design and analysis of epidemiologic studies aims at identifying risk factors and at evaluating the causal nature of their association with the disorder of interest.

A. Cohort study: design

E — D^- → D^+ / D^-

$\bar{E}$ — D^- → D^+ / D^-

t_0 → t_1 time
D^+ = disease onset
D^- = no disease onset

E = exposed
$\bar{E}$ = unexposed

B. Presentation of data

	Exposed	Unexposed
Events	a	b
Person – years denominator	N_e	$N_{\bar{e}}$

a/N_e = incidence among exposed subjects
$b/N_{\bar{e}}$ = incidence among unexposed subjects
IRR = incidence rate ratio $= \dfrac{a/N_e}{b/N_{\bar{e}}}$

FIGURE 3.2.1.2. Design (**A**) and presentation of data (**B**) in cohort studies.

Cohort Study

In cohort (or incidence) studies, the starting point consists of selecting two cohorts of subjects initially all free of the disease (Figure 3.2.1.2A). One cohort has experienced the exposure (exposed cohort) whereas the other (reference) cohort has not experienced it (unexposed cohort). Then, the person-time experience is measured in each cohort and the incidence of the disease can be estimated in each. The incidence in the exposed and unexposed cohorts is then compared by calculating an *incidence rate ratio* (Figure 3.2.1.2B) that is not different from 1 if there is no association between the exposure and the incidence. Conversely, if the exposure is

associated with an increased risk of the disease, the IRR will be higher than 1. When the measure of disease occurrence available is the cumulative incidence, the relative effect of exposure on the disease is estimated by the *risk ratio,* obtained by dividing the cumulative incidence in the exposed cohort by that from the unexposed cohort.

Cohorts are defined by the exposure status of their members. Sometimes, one single cohort will be available, but measurement of the exposure for each subject will allow the construction of two or several cohorts according to exposure levels (unexposed vs. exposed; or nil, medium, or high exposure). Cohort studies are difficult and costly to perform as they involve sometimes long periods of observation and therefore attrition can occur. One advantage of cohort studies is that several outcomes can be studied in relation to the initial exposure. Cohort studies are impractical if the disease incidence is low (rare disease), as the sample size required would be prohibitive. In some but not all studies, the investigator would be present at t_0 and wait for the cohort to mature (t_1) and live through the period at risk of developing the disease (*prospective cohort study*). In other studies (*retrospective cohort study*), the cohort study can be designed historically from data already collected. An example of this is the study showing a twofold increase in the risk of adult schizophrenia among subjects exposed to prenatal nutritional deficiency during the Dutch hunger winter in 1944–1945 (1), a finding recently replicated for the Chinese famine in 1959–1961 (2). Thus, the temporal position of the investigator regarding the data collection in a cohort study varies from study to study and is not what defines a cohort design. Knowledge of the biologic mechanisms that might underlie an association and of the disease model under investigation is critical in designing cohort studies. Some exposures might have a long induction period (e.g., parental loss in childhood in relation to adult female risk of depression), which must inform the precise delineation of the observational period and the data collection process.

Case–Control Study

In a case–control study, two groups are selected according to their present health status (with or without the disease of interest) and contrasted with respect to their past experiences of exposure to potential risk experiences (Figure 3.2.1.3A). Case ascertainment must be as complete as possible in order to represent the full spectrum of the disease and to avoid selection biases, particularly when case sampling is not independent of the exposure. Cases can be selected from the general population, but complete ascertainment may be difficult under these circumstances (i.e., identifying all cases of illness through hospitals, private clinics, and practices). Alternatively, cases may be selected in a cohort where more complete ascertainment can be achieved. Control selection is one of the most difficult design challenges in case–control studies. It is useful to conceptualize that controls should be selected from the

same source population from which cases arose; in addition, selection of controls should remain strictly independent from knowledge of their exposure status or level. Controls should therefore represent adequately the distribution of the exposure in the source population from which cases originated. Only when this is achieved can the case–control analysis evaluate if the exposure experience differs meaningfully between the cases and the controls. An implication for this conceptualization is that it is usually wrong to select controls among healthy volunteers who are likely to underrepresent the frequency of exposure (supernormal controls or healthy worker effect in occupational studies) in the source population and bias upward the estimates of association. Approaches to the selection of controls that rely on friends, neighborhood, or classroom controls are appealing due to their convenience but may also pose threats to the validity. Numerous examples of such problems are found in the psychiatric or psychological literature, when patient data are compared to healthy volunteer data (i.e., referred depressed adolescents compared to high school students) or other convenient series of controls (classmates, friends, etc.) leading to spurious “positive” findings (3).

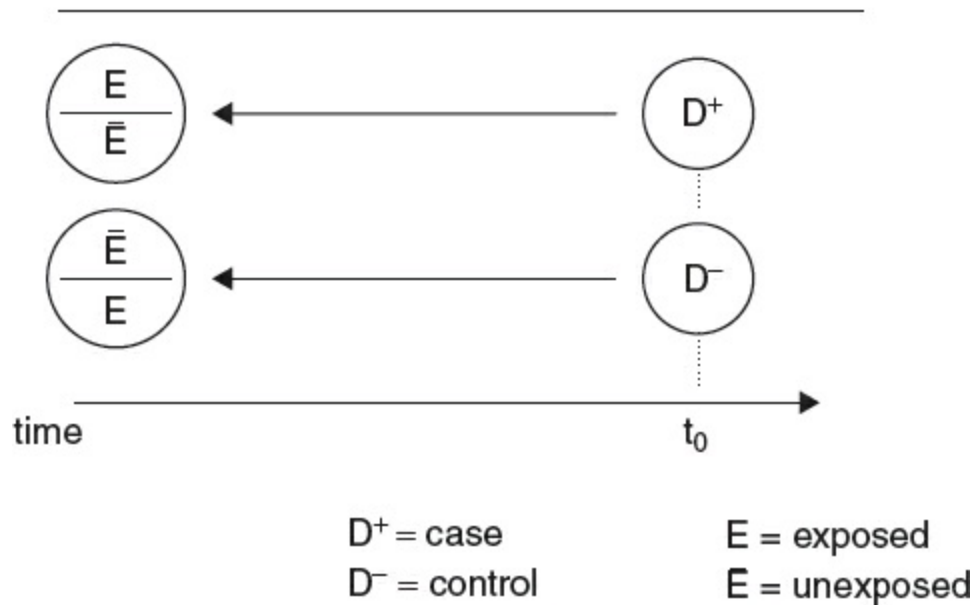
E / Ē ← D+

Ē / E ← D−

time → t_0

D^+ = case
D^- = control

E = exposed
$\bar{E}$ = unexposed


B. Case–control study: presentation of data

	Exposed	Unexposed
Cases	a	b
Controls	c	d

$$\text{OR} = \text{Odds–ratio} = \frac{a/b}{c/d} = \frac{a/c}{b/d} = \frac{a \times d}{b \times c}$$

FIGURE 3.2.1.3. Design (**A**) and presentation of data (**B**) in case–control studies.

To address the difficulty of control selection, two or more control groups may be selected that differ for their selection procedure and thus for the possible sampling biases that they each introduce. While intellectually appealing, this approach may be practically very labor intensive. Furthermore, there is no guarantee of the absence of bias when similar estimates are obtained when comparing the case series to each control group; conversely, if diverging estimates are obtained with each control group, the investigator is left with the difficult (and often impossible) task of determining where from and in which group the source of bias operates.

Exposure data are often (but not necessarily) collected retrospectively, making case-control the study vulnerable to measurement biases due to differential recall (or recall bias) or missing data. For example, when interviewed and compared to nondepressed controls, currently depressed individuals might overreport past

negative life experiences simply because their threshold for remembering and evaluating as negative particular events might be affected by their current mood state.

Incidence rates are not available in a case–control study; estimates of the association between the candidate risk factor and the disease are calculated by comparing the odds of exposure among the cases and the controls (Figure 3.2.1.3B). One sometimes calculates the case/control ratio among exposed (a/c) and unexposed subjects (b/d), which leads mathematically to the same computation of the odds ratio. This calculation also illustrates how case–control studies converge toward cohort studies when controls provide an adequate representation of the exposure distribution in the source population (i.e., when c and d converge toward N_e and N_{e^-} (see Figures 3.2.1.2B and 3.2.1.3B)). The resulting odds ratio (OR) is an estimate of the incidence rate ratio obtained in cohort studies. Case–control studies can be performed more rapidly and are efficient. They are particularly indicated for rare diseases. Case–control studies also allow for the evaluation of several exposures in relation to a given disease.

Cross-Sectional Study

Cross-sectional studies are studies of large and representative samples of populations at a given point in time. Usually, disease status and exposure status are measured at the same time, and these data can then be used to calculate prevalence rates and prevalence rate ratios. Prevalence rates can be informative for planning and services purposes. Prevalence rates can also be compared in various subgroups of the population (males vs. females, high or low SES, rural vs. urban, etc.) in order to identify characteristics or risk factors associated with disease status. Limitations of cross-sectional studies are that duration of the disease and other factors (earlier diagnosis, efficacious treatments, etc.) unrelated to disease onset influence the size of the prevalence pool (see section on 'Prevalence').

Ecologic Study

In ecologic (or aggregate) studies, the unit of observation is the group rather than the individual. The level of analysis could be classrooms, schools, neighborhoods, municipalities, states, or countries. If both exposure and health outcome data are available at that level of analysis, their relationships can then be examined. For example, county suicide rates could be positively correlated with county unemployment rates, suggesting that unemployment leads to suicide. However, the joint distribution of exposure and disease is generally not known at the individual level, and it is possible that those individuals who commit suicide are not those who are unemployed (e.g., suicide might be occurring among young people, whereas unemployment would affect those over age 50). This interpretation problem has been identified as the *ecologic fallacy* or ecologic bias. In these studies, information about

confounding factors (age, in the previous example) is usually very limited; in addition, the temporal sequence between disease events and exposure (that must precede the health outcome) can be difficult to determine. Ecologic studies have the advantage of being simple and cheap to perform considering the wide availability of vital statistics and sociodemographic indicators in many countries. Time trend analyses and cross-national comparisons are also forms of ecologic studies that may yield useful information not readily available otherwise. Ecologic analyses can also be informative in circumstances where levels of individual exposure lack variability (i.e., all individuals in a population are unexposed or all are exposed). For example, studies examining risk of autism in relation to exposure to vaccination might be uninformative if every child in the study population has been vaccinated. Comparing rates of autism in areas or time periods that *differ* for their rates of vaccine uptake (an ecologic comparison) might be the most informative approach. For example, rates of pervasive developmental disorders (PDDs) increased in Quebec from 1987 to 1998 but, as levels of exposure to thimerosal through vaccines varied from medium to high and then nil during the same period, investigators used this natural experiment to show that trends in PDD rates were unrelated to exposure to varying thimerosal levels (4). In some investigations, ecologic effects are also the focus of interest even when individual-level data are available. For example, one might want to examine the respective contribution to the individual risk of engaging in antisocial behavior from both child and familial characteristics (individual level) and of community characteristics (group level). Multilevel analyses of that kind have often been conducted in the social sciences.

Other Designs

Other study designs or mixed designs can be used in epidemiology. For example, a case–control study can be *nested* in a cohort study, which provides opportunities to ascertain a representative sample of cases and of controls and to rely on prospective (less biased) measurements of risk factors. In that instance, the case–control study would be referred to as a *prospective* case–control study owing to the fact that the measurement of risk factors *precedes* that of the onset of disease. Other study designs are discussed extensively elsewhere (5).

Issues of Sampling and Data Analysis

Sampling

In large population-based cross-sectional surveys that have been typical of psychiatric epidemiology in the last 40 years, sampling techniques vary from simple random sampling (SRS) to more complex stratified or cluster sampling strategies that aim to increase the precision of estimates, while optimizing survey resources and

reducing costs. A typical example of a complex survey design would be a survey where two strata defined by the type of classrooms (special education vs. mainstream) are selected and children from special education classrooms are sampled with a higher sampling fraction than their counterparts. In addition, if all the subjects within each classroom are selected, the natural occurrence of these clusters must be taken into account, as observations are no longer independent (the same would apply to household surveys). For example, the same teachers would be providing data on several children who also happen to share common experiences that may be determinants of behavioral disorders (teaching quality, physical characteristics of the classroom).

In selecting children for inclusion in the study sample, it is crucial to note the probability of each child being selected, so that subsequently these probabilities can be used to weight back the observations (usually with weights that are the inverse of the sampling fraction) for extrapolation to the target population. This allows oversampling of some subgroups without distortion of the final estimates, provided that proper weights are devised and applied. Taking into account the clusters and strata used initially as sampling frames is also required in order to derive unbiased variance estimators. The analysis of two-phase or more complex survey designs is discussed further by Dunn et al. (6).

Registers or Population-Based Electronic Databases

Registers are data collection systems maintained by administrative or public health authorities over time to monitor health indicators. Several psychiatric case registers exist that have been used in epidemiologic investigations. When well maintained, they can provide an easy way to access potential participants and an efficient sampling source, from which various case–control or cohort studies can be derived in no time. Thus, national health and psychiatric registers available in Denmark or the General Practitioner Database in the United Kingdom have been invaluable tools for epidemiologists to allow them to test rapidly emerging hypotheses, such as on the risk of autism in relation to exposure to measles–mumps–rubella (MMR) vaccine, or to the thimerosal content of children's immunizations. Different research designs were used from those sources, and including cohort (7,8), case–control (9) or ecologic (10) studies, all of which failed to detect any association.

Sample Size and Precision

In each study, the goal is to estimate rates or measures of association with as much precision as possible. Precision is decreased by various sources of random error, including imperfect measurements of exposure or disease status (see below), or sampling errors. In order to limit the loss of precision due to sampling error, increasing the sample size is a common technique that involves detailed calculations

at the designing stage of the study that consider cost of sampling, sample availability, and preliminary estimation (based on past studies or conceptual considerations) of the likely range of values for the rate differences or risk ratios to be estimated. A tradeoff between gaining more precision by increasing sample size and the expanding costs of the study is often a consideration. In some case–control studies, the study efficiency can be tremendously improved by selecting several controls for each case. This would apply to circumstances where the number of available cases is limited, more statistical power is required, and controls are ubiquitous and cheap to obtain. Matching up to four or five controls to each case would maximize the power of the study. Beyond that number, the gains of matching extra controls become rapidly smaller and not worth pursuing.

Missing Data

Methods for dealing with missing data are crucial and have been addressed more efficiently in recent surveys. Participation rates in child psychiatry surveys have generally been high, often well over 80%. Bias in the estimates of prevalence and risk associations might result, nevertheless, if those who do not participate have higher rates of disorders, more severe disorders, or disorders arising through different mechanisms. Empirical findings indicate that nonrespondents often differ systematically from respondents. For example, in a survey of school-age children, behavioral disturbances reported by teachers were 60% higher among nonparticipants than participants, but survey weights could be used to correct for this bias in the final prevalence estimation (11). Similarly, attrition bias in longitudinal studies may attenuate predictions regarding the persistence of disorders over time (12).

Missing data can also occur at the item level, with respondents omitting items on a checklist or failing to answer all questions in an interview. This may jeopardize data collection (if incomplete screens are deemed ineligible for further interview) or analysis (if incomplete interviews are not dealt with separately). Sophisticated statistical and imputation techniques are available to take account of missing data, different according to the reasons that they are missing (13,14).

Statistical Testing

Point estimates of disease occurrence (incidence, prevalence) and of measures of association (relative risks, such as rate, risk, and odds ratios) derive from the particular samples studied by investigators. The values obtained in one study are meant to be robust and unbiased estimators of the true population value, also called population parameters. In any one study, there is imprecision attached to each point estimate and epidemiologists communicate findings with 95% confidence intervals calculated around point estimates. For example, the odds ratio in a case control study

could be expressed as: OR = 2.2 (95% confidence interval: 1.5–3.4). A 95% confidence interval can be construed around all measures of disease occurrence and of association reviewed earlier. Confidence intervals provide a range of values that are consistent with the true population parameter under the present study circumstances. For measures of association, a relative risk of 1 is the expected value under the null hypothesis of no association between the exposure and the disease. If a 95% confidence interval around a point estimate for the relative risk includes 1, the null hypothesis is not rejected. If 1 is not included in the 95% confidence interval (as in the above example), the null hypothesis is rejected at the 0.05 significance level. Too much emphasis is sometimes placed on statistical testing. Statistical testing is necessary in circumstances where decisions must be made (treat this patient or not). In most studies, epidemiologists are interested in evaluating causal relationships, and a probabilistic rather than a black and white (significant or not) approach to this problem is warranted. Suffice it to remember that a very small effect (OR = 1.2; 95% CI: 1.05–1.45) of unlikely biologic or clinical relevance could reach statistical significance only because the study has huge statistical power due to a very large sample size. Conversely, a larger, but statistically not significant, effect (OR = 2.9; 95% CI: 0.9–5.4) could point toward true associations of moderate magnitude. In those circumstances, epidemiologists who pursue causality will pay more attention to the strength of the association (the point estimate) and its interpretability in the larger context of the study design and findings. Causality assessment is better viewed as an ongoing, continuous, interpretative process that might be jeopardized with premature decision making rules embodied by classical statistical significance testing.

Bias and Confounding

Whereas sample size can influence the precision of a study, sample selection can limit the validity of the estimates obtained by introducing systematic (as opposed to random) error in the rate or risk ratio estimates. Various other sources of bias are well recognized in epidemiology, which are also briefly described here.

Selection Bias. Selection bias occurs when subjects who participate in the study differ systematically from the population that they represent for characteristics associated to the disease or exposure under study. Several examples have been discussed above. One other example of selection bias is selective attrition when, in a cohort study, subjects who are lost to follow-up differ from the cohort subjects with respect to the incidence of the disease. Migration in or out of a population or differential mortality are similarly potential sources of bias. When selection biases of that kind are suspected, it is critical for investigators to use baseline data to empirically test whether or not subjects lost to follow-up are systematically different from those who are not. Selection biases are a particular concern in case–control studies, especially with respect to the selection of controls.

Information Bias and Misclassification. A valid measure of the association between the exposure and the disease depends on the accuracy of measurement of both variables. Due to measurement error, a diseased subject could be classified as control, or an unexposed subject as exposed. Measurement errors on dichotomous classifications of exposure and disease status are described with concepts of sensitivity and specificity (see below). Classification errors are referred to as *misclassification* and a more general discussion of measurement principles and errors as it applies particularly to psychiatric research is provided below.

In an epidemiologic study where the goal is to estimate an association without bias, a critical feature of misclassification is whether or not it occurs independently of other variables. *Differential misclassification* occurs when the measurement error affects cases or controls, or exposed versus unexposed subjects, with different patterns. A typical example of differential misclassification is recall bias. For example, in a case–control study of a severe birth neurodevelopmental abnormality of unknown origin at the time, mothers of cases reported significantly more psychosocial stressors during pregnancy (financial difficulties, marital difficulties) than mothers of controls (15). This suggested that psychosocial stress could be a cause of the negative birth outcome. It turned out that the abnormality was Down syndrome, the chromosomal etiology of which was only discovered in the months that followed. The only explanation for the spurious association between Down syndrome and psychosocial stressors during pregnancy in Stott's study lies in the differential reporting by mothers of cases (in search of a cause for their child's anomaly) of their past psychosocial experiences. It is important to consider that measurement error itself is not the problem if it affects subjects across groups equally. The bias arises from the fact that cases and controls do not report their exposure experience in a comparable fashion. Recall bias is a well-recognized problem of retrospective case–control studies that can be addressed and prevented. For example, obtaining evidence from other sources of information, preferably collected before the onset of the disease (past medical or educational records), or through informants who are blind to the case status of study subjects, would limit the possibility of differential misclassification. Differential misclassification can inflate measures of association as in the previous example, or it may also attenuate them.

Nondifferential misclassification occurs when classification errors on exposure or on disease occur independently of each other. This type of misclassification almost always attenuates measures of association and biases the study results toward the null hypothesis of no association between the exposure and the disease. For example, in a case–control study free of measurement error of 200 depressed adolescents compared to 200 nondepressed controls, the presence of two or more negative life events (LE+) compared to one or less events (LE−) in the 12 months preceding the onset of depression is a risk factor for adolescent depression, with the ratio of exposure (LE+/LE−) being 80/120 in the cases and 40/160 in the controls,

which translates into an odds ratio of 2.7 (see Figure 3.2.1.3B). If one assumes now that life events are measured with an imperfect questionnaire method that misclassifies 20% of subjects truly LE+ as LE− and 20% of subjects truly LE− as LE+, and that this occurs equally among cases and controls (the misclassification is nondifferential, as it is independent of disease status), the ratio of exposure (LE+/LE−) is now 88/112 in the cases and 64/136 in the controls, which translates into an odds ratio of 1.7. In this example, the odds ratio is biased toward the null value of no association due to an unwelcome mixture of exposed and unexposed subjects in both cases and controls that blurs the true contrast of exposure distribution that exists between cases and controls in the absence of measurement error. Similar biases would occur if nondifferential misclassification were applied to disease status. In general, therefore, nondifferential errors must be discussed in relation to negative studies or studies with associations of small magnitude. Differences in the error rate of measurement across studies may explain inconsistent or discrepant findings. In psychiatry, reliance on questionnaires and interviews, on lifetime measures of risk or disease experience, and on broad diagnostic groupings, are potential sources of considerable misclassification.

Confounding. Confounding factors are variables that may be responsible for a distortion of the relationship between the exposure and the disease. As such, confounding factors might over- or underestimate an association, and sometimes may even change the direction of the association. Confounding variables operate in all study designs, including in experiments. However, methods exist in experimental research (e.g., randomization) to limit the distorting effects of confounding factors. In nonexperimental designs, the control of confounding factors may be more difficult to achieve. To be a confounding factor, a variable must be shown (or known) to be associated with both the exposure and the disease independently. Furthermore, a confounding factor cannot merely be an intermediate variable in the causal chain linking exposure to disease. In a study where smoking during pregnancy is associated with later behavioral problems in the child, maternal antisocial behavior is a likely confounding factor. Maternal antisocial behavior is associated to smoking during pregnancy, and quite separately, it is associated with increased risk of child behavioral problems independently of its association to maternal prenatal smoking. Thus, the association between prenatal maternal smoking and later child behavioral problems could be entirely accounted by the confounding effects of maternal antisocial behavior. In other words, the co-occurrence of smoking and behavioral problems could be artefactual and entirely driven by their background association to maternal antisocial behavior.

Confounding factors must therefore be dealt with both at the planning and analysis stages of a study. When designing a study, it is important to include in the data collection careful and valid measurements of potential confounders. Confounders can

be identified a priori by investigators based on past studies or on theoretical and biologic knowledge about the disease and risk mechanisms under scrutiny. Another strategy is to restrict the study to particular subgroups using exclusion criteria. For example, gender would be recognized as a potential confounding factor in a study examining the relationship between plasma levels of sex hormones and adolescent depressive symptomatology, since gender is associated with sex hormone levels and with the risk of depression. Restricting the study to females only is an effective solution but it has the disadvantage to limit the degree to which the findings can be generalized (nothing can be said about males). Another approach used by epidemiologists consists in stratifying the data at the analysis stage to obtain unconfounded stratum-specific estimates of the association that can be subsequently pooled together. Other techniques rely on statistical modeling, and techniques such as multiple logistic regression are often used to adjust the measures of association and remove the effects of confounders on the estimates. Detection, measurement, and adjustment on confounding factors is an important task of investigators that is never ending. Thus, it always remains possible in every study that an observed association is explained by residual confounding effects or by unobserved and unmeasured confounding variables. Thus, replication of associations across studies is important to offer additional evidence for the validity of an association.

Causality Assessment

Risk Association and Causality Assessment. Measures of association in epidemiologic studies (risk and odds ratios) are tested for statistical significance. When the risk or odds ratio departs sufficiently away from the value 1 that is expected under the null hypothesis, the null hypothesis of no association between the exposure and the disease under study can then be rejected. Two important features of this conclusion are to be noted. First, a significant association between exposure and disease reflects a statistical association between two variables. Demonstrating that this association is also causal is the ultimate goal of the epidemiologist, but requires several other types of evidence than a “statistically significant” result. Second, like statistical tests, the conclusion of epidemiologic studies is asymmetrical. When the study fails to detect an association (the null hypothesis is not rejected), it cannot be regarded as proof that no association exists in the nature. Rather, the lack of association could reflect poor research design, sampling bias, or nondifferential misclassification. Conversely, when a significant association is reported, epidemiologists reject the null hypothesis of no association but causality cannot generally be definitely inferred from that conclusion.

Hill’s Criteria. Stronger evidence for a causal association can nevertheless be evaluated using different sets of criteria. Hill (16) laid out nine criteria that he proposed as guides for evaluating the causal nature of an association. There are: (1)

strength of the association, where higher odds or risk ratios are more likely to indicate a causal relationship; (2) consistency, where an association is replicated in different samples studied with different methods; (3) specificity, where causality is more likely if the association between the exposure is confined to that disease, as opposed to leading to multiple, unrelated, negative outcomes; (4) dose–response, where the risk of the disease increases with increasing levels of exposure; (5) temporality, where the exposure must precede the onset of disease in order to be causal; (6) plausibility, whereby the association could be referred to a biologically plausible mechanism; (7) coherence, where the causal nature of the association must be consistent with other aspects of the biologic knowledge available about the disease; (8) experimental evidence, where the association is supported by the results of experimental manipulations of the exposure (in laboratory or human experiments, or field studies); and (9) analogy, when comparable associations can be identified in other domains of inquiry. Perhaps with the exception of the criterion of temporality, none of Hill's criteria is sufficient or necessary to establish causality. Thus, they should not be used as a mechanical checklist to "add" to the causal evidence, but simply as a set of arguments that may (or not) guide the interpretation of a given result.

Replication. An important argumentation for evaluating causality lies in the replication of findings across studies, preferably performed by different investigators, in different populations, and with different instrumentation. If findings converge (either for or against association) in studies that are otherwise likely to differ drastically in their potential sources of bias and imprecision, then the confidence in the interpretation increases substantially (although there remains no definite proof). For example, the recent hypothesis linking autism to exposure to the measles component of the MMR vaccine given to children in their second year of life was extensively tested by different epidemiologic approaches that included cohort (7), case–control (9,17), and ecologic (4) designs that failed to reject the null hypothesis of no association. The consistent failure across studies to find a positive association should be taken as stronger evidence of the lack of association than that deriving from each study taken in isolation. Conversely, consistent positive associations between an exposure and a disease across studies strengthen the argument for causality. Meta-analysis is a technique that provides a quantitative route toward evaluating jointly the evidence arising from separate studies.

Public Health Relevance of Epidemiology

Epidemiology is the fundamental discipline of public health insofar as both the research methodology and the substantive findings of epidemiologic studies are necessary to inform public health activities. Surveillance by public health agencies such as the Centers for Disease Control (CDC) is critical to the monitoring of the

health of a population and for identifying variations in time and place in rates of disorders. Surveillance systems are also critical to respond to the emergence of new diseases (as in the AIDS example) or to changes in the incidence or prevalence of known illnesses or disorders (as suggested recently for autism). Vital statistics, including morbidity and mortality reports, have been traditional ways to monitor population health. They are often supplemented by specific and repeated surveys of disorders or events of importance for public health. Public health agencies also have the task to implement and evaluate universal or targeted preventive programs. Evaluation of models of service delivery, factors influencing access to health care, and more generally health services research, are public health activities that require the knowledge bases and contribution of epidemiologic methods and studies.

Examples of the contribution of child psychiatric epidemiologic studies to public health and surveillance programs are found easily. Several surveillance systems are in place in the United States to capture trends in child psychiatric disorders or problem behaviors. For example, as part of the Monitoring the Future Study, annual surveys of large samples of high school students have been conducted since the 1970s to monitor rates of marijuana and other drug use. From the early 1990s onward, the CDC Youth Risk Behavior Surveillance System (YRBSS) have performed national, state, and local school-based surveys conducted by education and health agencies to monitor several categories of health-risk behaviors, including unintentional injuries and violence, tobacco, alcohol and other drug use, risky sexual behaviors, and suicidal behaviors. These surveys have been instrumental in showing that annual rates of suicide attempts are around 8%, affecting a substantial minority of teenagers. Monitoring time trends in the incidence of disorders has also been possible with epidemiologic studies that relied on registers to identify cases over several decades. Thus, the Mayo Clinic register in Rochester, MN, has allowed investigators to detect changes in the incidence of disorders such as anorexia nervosa (18) or autism (19). Recently, the CDC has started a surveillance program of autism and related disorders in response to worldwide concerns about a possible increase in the incidence of autism spectrum disorders.

CHILD PSYCHIATRY EPIDEMIOLOGY

Brief History and Landmark Studies

Child psychiatric epidemiology started in the mid-’60s with the British Isle of Wight surveys (20,21). Prior to this landmark study, there had been few investigations of rates of behavioral problems in general population samples of children. One such survey emphasized the high prevalence of fears and worries and the discrepancies in rates of problems according to the informant (22). Most knowledge at the time relied on observations drawn from clinical case series. Behaviors were interpreted and

theoretical inferences were made without having a proper calibration system of those behaviors that discriminated best between children seen in clinics and nonreferred children. Epidemiology, with its focus on general population samples and on comparisons between individuals with or without disorders, provided an obvious tool for the empirical investigation of child psychopathology.

The Isle of Wight surveys had key design characteristics that provided a model for surveys in the years after (23). A two-phase design was used with a systematic questionnaire screening of a large sample, followed by indepth assessments administered only to a subsample selected according to their positive and negative results at screening. Multiple informants were used at both phases, involving parents, teachers, and children. The value of asking direct questions to children was established and interviews subsequently replaced the old indirect techniques (projective tests and free play) as investigation tools. Questionnaires and diagnostic interviews of known reliability and validity were employed for the first time to gather data. *Caseness* was defined according to both a recognizable behavioral pattern *and* evidence of impairment in the child's functioning. The surveys also adopted longitudinal approaches to measure prospectively risk factors and chart the natural history of disorders, and to evaluate which behavioral outcomes were related to neurologic and educational risk factors (21). These methodologic advances have been developed further in surveys conducted since. Two-phase designs are cost-effective ways to conduct cross-sectional surveys of large population-based samples and they have been employed in numerous child psychiatry epidemiologic investigations (Table 3.2.1.1). However, the value of longitudinal studies has been increasingly recognized by developmental psychopathologists and, wherever feasible, cohort or longitudinal approaches are preferred to study causal mechanisms underlying the onset, persistence, and desistance of and from psychiatric disorders.

Measurement in Psychiatry

The planning of epidemiologic studies requires precise methods to ascertain "cases" of the disorder under study (40). A definition of "caseness" must be adopted at the outset. Its nature should be shaped by the goals of the survey. A survey of autism to identify representative cases for inclusion in genetic studies will require detailed phenotypic assessments, precise diagnostic subtyping, and exclusion of autistic syndromes associated with known medical disorders. If, on the other hand, the goal of the autism survey is to generate estimates of special educational needs for service planning, then a less restrictive and broader approach to caseness may be more suitable. Following the adoption of the most appropriate concept of the disorder, decisions must be made about the choice of various assessment procedures and instruments to evaluate caseness in study participants.

Definitions of Caseness

All epidemiologic surveys have shown the high frequency of individual emotional or behavioral difficulties (20,41). However, whereas some have a strong association with psychiatric disorder, others do not. Thus, in the Isle of Wight survey, thumb-sucking, nail-biting, and bilious attacks all had very weak associations with psychiatric disorder (20). Similarly, item scores for *Asthma* and *Allergy* have been removed from the computation of the total score of the Child Behavior Checklist after consistent evidence that these were not associated with psychiatric referral. By contrast, the symptom of *Depressed mood* has been shown to account for much of the variance in comparisons of matched samples of nonreferred and referred children (41,42).

However, continuities and discontinuities between individual symptoms and disorder may involve crucial transitions. Thus, depressed mood is experienced by about a third of adolescents in the general population (43) but the rate of depressive disorder is only about 5%. Similarly, some half of female adolescents diet, but anorexia nervosa occurs in less than 1% (44). The situation with substance use and abuse and with disruptive behavior is directly comparable. Many problem behaviors have a continuous distribution in the population and quantitative, rather than qualitative, deviance often defines psychopathology.

Dimensions and Categories

Because of this, most epidemiologic studies use a mixture of dimensional and categorical approaches. The former are needed both to assess symptom severity and to allow the adoption of different cutoffs for different purposes. The latter is required for clinical decision making with respect to individual diagnosis and service planning. The issues are not specific to psychopathology; rather, they apply throughout most of medicine (as exemplified by asthma, hypertension, diabetes—all of which have dimensional parallels). Sometimes it is assumed that dimensional measures are synonymous with questionnaires and categorical ones with interview assessments, but that is not so. All standardized interviews provide for various forms of quantification of severity or numbers of symptoms. Conversely, most questionnaires provide the means for deriving categories from dimensional scores with appropriate cutoff points.

Careful consideration of instruments characteristics is critical in planning an epidemiologic study (Table 3.2.1.2).

Obviously, that choice should be driven by the main purposes of the study. Questionnaires have all the advantages of economy and simplicity and may be the first preference if the goal involves only group differences and trends. They will almost always be used in the first screening phase of multistage studies. On the other hand, they are less suitable for individual diagnosis or for the assessment of

uncommon disorders involving qualitative departures from normality. Standardized interviews have the opposite set of strengths and weaknesses. The chief decision issue with interviews is whether to use an investigator-based (semistructured) interview that obtains descriptions of behavior that are rated using a standardized research-driven concept or a respondent-based (structured) interview that obtains yes/no answers to carefully structured questions. Each has its own merits and researchers will need to consider carefully which is most likely to meet the needs for the particular investigation to be undertaken. A further decision is needed on whether to choose a broad-based measure designed to tap all the common varieties of psychopathology or rather to use one or more focused instruments. The former will meet most needs but are less suitable for uncommon or unusual disorders such as autism, schizophrenia, or Tourette syndrome. Whatever the particular choice of instrument, investigators will usually need to test their chosen set of measures and data collection procedures in pilot studies of adequately sized samples to determine the procedural feasibility and its acceptability by respondents. Pilot studies should be analyzed carefully using quantitative methods whenever possible.

C, based on child as informant; P, based on parent as informant.
[a]Any depressive disorder;
[b]Any anxiety disorder.
[c]Any serious emotional disturbance.

Situation Specificity, Multiple Informants

From the Isle of Wight studies onward, it has been evident that the agreement on childhood psychopathology between different informants is typically low, and is only moderate at best. Thus, in an epidemiologic survey of 6 to 11 year olds, only a quarter of children scoring above the cutoff on at least one screening measure were scoring above threshold on both parent *and* teacher questionnaires (45). In a meta-analysis of 119 studies, Achenbach et al. (46) found that the agreement was best (circa .60) when the pairs of informants had similar roles in relation to the child (such as with mother–father or teacher–teacher), whereas the mean correlation fell to the .20s for other pair types (such as parent–child or parent–teacher).

TABLE 3.2.1.2

CRITERIA FOR SELECTING AN INSTRUMENT

	Interview	Questionnaire
Purpose	Screening/Diagnosis	Screening/Assessment
Main use	Epidemiologic/clinical	Epidemiologic/clinical
Reliability	Test—retest	Test—retest

	Interrater	Split-half, internal consistency
Validity	Content, discriminant, concurrent, predictive	Content, discriminant, concurrent, predictive
	Cross-cultural	Factorial/construct validity Cross-cultural
Coverage/content	Diagnostic categories Number of disorders	Psychopathologic constructs Number of items
Method	Face-to-face interview	Self-report (usually) or other informant (parent, teacher, clinician)
Response format	Yes/No (highly structured) All informants' descriptions (semistructured)	Interval Likert scaling Visual analogue
Completion time	Long (hours)	Brief (minutes)
Informant	Subject	Subject (over 10 yrs)
	Parent	Parent, teacher
	Other	Clinician, interviewer, other
Time frame	Current (last 3 or 6 mo)	Current, last week
	Last year	Last 3 to 12 mo
	Lifetime	
Age assessed	Depends on informant and content	Depends on informant and content
Training	Required clinical for semistructured, basic for highly structured	None (self-administered) or minimal (interviewer-assisted)
	Availability of training packages	Literacy requirement
	Availability of manual	Availability of manual
Version	Paper & pencil	Paper & pencil
	Computer assisted	Computer administered
	Computer administered	
Data entry	Laborious (unless computerized)	Easy (optical forms)
Scoring	Diagnostic algorithms	Norms, centiles, cutoffs
Costs	High	Low
Repeat assessments	Modularity of the interview	Easy, demonstrated sensitivity to change
	Scale scores available	
Extra features:		
other domains	That is, personal and family details, impairment, burden, etc.	That is, personal and family details, scholastic achievement, etc.
suitability for longitudinal studies	Adult diagnostic interviews	Parallel adult forms
observational assessments	Companion observational schedule	Parallel observational scale
cultural context	Availability in other languages	Availability in other languages
	Validity in different populations	Validity in different populations

There are many possible reasons for this low agreement between informants. These include random error in measurement; different perceptions of behavior according to the perspective of the observer; different frames of reference and variations in the child's behavior according to both setting and interpersonal features. The relative importance of these different possibilities is not known. However, it is

clear that multiple informants are essential for any adequate epidemiologic study. That is partly because each informant contributes uniquely to the measurement of psychopathology (as well as contributing to shared variance); because when studying the correlates of disorder it is necessary to go across informants (or use composite ratings) in order to avoid halo effect artifacts; and because of the importance of differentiating between situation-specific and pervasive disorders.

That leaves open the crucially important (but largely unresolved) question of how to combine the data from different informants and from different settings. Although there is some evidence that different informants have different strengths, only rarely will it be desirable to adopt a hierarchical approach in which the report of one informant is automatically given precedence over those of others. Nevertheless, child self-reports are particularly important for the assessment of mood and other emotional disturbances. Conversely, they are of very limited use for the assessment of hyperactivity. Similarly, teachers are generally better at the assessment of disruptive behavior than they are of depressed mood. As the findings from Verhulst et al. (33) show dramatically (see Table 3.2.1.1), prevalence estimates are often hugely affected by how multiple ratings are dealt with.

Clinical interviewers usually use their “best” judgment in order to weigh the symptoms endorsed by each informant, resolving discrepancies by personal rules derived from a combination of experience and theoretical predictions. That is likely to result in different clinicians combining data in different ways. Another approach is trying to seek to resolve discrepancies between informants through a conjoint interview involving different informants (such as parent and child). This might be helpful in eliminating some errors due to miscomprehension and in “reconciling” the informants (47); however, the method is far from free of problems, most especially in giving rise to delicate situations that threaten to breach confidentiality. Nevertheless, this judgment method is recommended for some diagnostic interviews, such as the K-SADS (48), in order to allow the generation of a single unique score for each symptom rating. A third commonly used approach uses computer generation of diagnoses based on predefined algorithms. The method has the advantage of accuracy and speed. The algorithms must, however, deal with differences in reporting by informants according to specified rules. Usually, a symptom is counted as positive when it is reported by at least one informant—the so-called “or” rule (49). This technique typically leads to high numbers of generated diagnoses “comorbidity.”

For dimensional assessments, Achenbach (50) has revised the data collected through his set of questionnaires in order to solve this cross-informant problem. Based on systematic analyses of the CBCL, the TRF, and the YSR, he identified common syndromes on each of these questionnaires, and core syndromes that appeared consistent across sex and age subgroups. Then, a set of cross-informant core syndromes that spanned at least two instruments was selected. These were subsequently scaled with the relevant normative samples. This approach does not

resolve the problem of how to combine data from discrepant informants, but it helps in increasing the interpretability of a profile of scores for a given child (51,52). More sophisticated statistical techniques are available to researchers to deal with the measurement problems associated with multiple data sources and discrepancies between informants (see below), or are being developed (53).

Reliability and Validity Principles

At the core of medicine, and of any scientific inquiry, is the activity of measurement. Measurement theory (Figure 3.2.1.4) is concerned with defining and strengthening the relationships linking empirical or observable indicators (I1, I2, etc.) to the unobserved or latent constructs (V1, V2, etc.), that they intend to measure. In psychopathology, many constructs cannot be easily observed (such as self-esteem, personality traits, feelings of guilt, etc.). To address this gap, interviews, questionnaires or tests have been developed and evidence exists that their empirical results (whether those are signs, symptoms, algorithm or test scores) can be confidently related to the unobserved constructs of interest. Far from being a question restricted to research, the same requirements apply to everyday clinical practice. Clinical judgment is just one tool available to measure patient status, and as such, its measuring properties should be scrutinized and demonstrated. Thus, the choice is not between measuring or not (or between research and clinical practice), but rather between measuring with known and replicable procedures or with unspecified and imprecise approaches.

Two major properties, validity and reliability, are key features of assessment procedures (clinical or research instruments, but also the simple clinical judgment) for which Figure 3.2.1.4 provides a convenient representation. Data collected as part of clinical or research assessments can be seen as empirical indicators of the underlying (unobserved) constructs of interest.

Reliability is the tendency of measures to yield consistent results over repeated trials. Reliability concerns the replicability of measures and the extent to which each measurement is affected by random error. Reliability can therefore be examined empirically (see bottom level on Figure 3.2.1.4). Typical procedures to estimate reliability are the test–retest paradigm, interrater agreement, and techniques based on correlations between subsets of instruments (split-half reliability), or among items composing a questionnaire (internal consistency). The reliability of the measurement is assessed within each procedure by specific statistics such as the kappa coefficient for categorical measurements (54), the intraclass correlation coefficient for quantitative scores (55), and other statistics (e.g., Cronbach's (56) alpha coefficient). Reliability is a necessary condition, but not a sufficient one, for validity. If empirical indicators are unduly contaminated by random error (so that measurements cannot be replicated), then the question of their relationship to the constructs (the validity question) that they are purported to tap cannot even be assessed meaningfully. On the

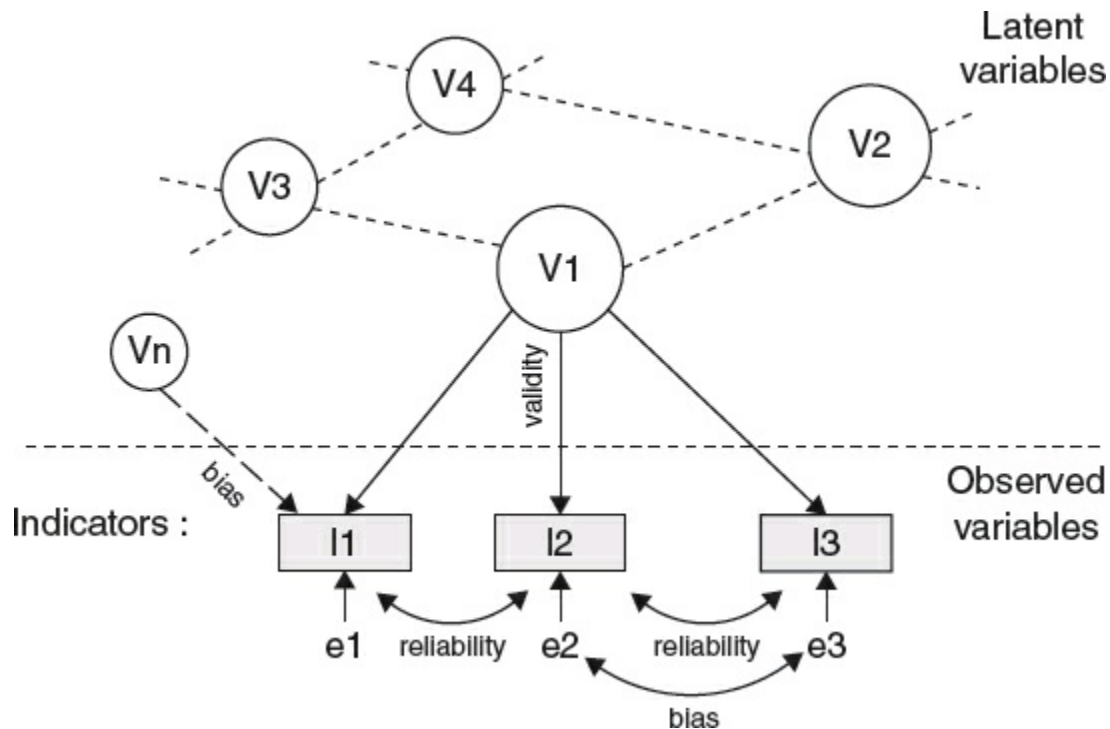
other hand, high replicability does not necessarily mean good validity.


FIGURE 3.2.1.4. Measurement model.

Validity concerns the crucially important relationship between the empirical observables and the postulated latent construct (a diagnosis, a psychological concept, etc.) as represented by the connections between the bottom and top levels on Figure 3.2.1.4. Several types of validity have been described. *Content* validity is concerned with the extent to which an instrument is representative of the universe of empirical indicators that are related to the concept measured. It is usually assessed by reliance on experts or on agreement with established instruments tapping the same concept. *Criterion-related* validity is the most empirical form of validity. It allows an index or score to be compared to an independent external criterion thought to assess the same concept. This can be either *concurrent* (high stress predicts cortisol levels) or *predictive* (IQ predicts later academic achievement). *Construct* validity is the most elusive and theoretical type of validity. Basically, it concerns the extent to which individual items or measures intercorrelate or group together to produce derived higher order constructs. Factor analysis has often been used for this purpose in the field of psychopathology. Thus, numerous factor analyses of questionnaires have consistently identified separate dimensions (or constructs) of psychopathology (such as attention problems, conduct symptoms, or emotional disturbances). These tend to map onto a broad bipartite division into internalizing/emotional problems and externalizing/disruptive behaviors (57,58). Consistency of these factor analyses results has been taken as evidence of the construct validity of these psychopathology dimensions.

Diagnostic Reliability and Validity

In psychiatry, multiple efforts have been made to evaluate and improve the properties of psychiatric diagnosis. Since the first collaborative efforts sponsored by the World Health Organization to improve diagnosis in psychiatry, reliability studies have been undertaken to examine interrater agreement and to improve the definition, and thereby the diagnostic reproducibility, of disorders (59). In the late 1970s, with the development of research diagnostic criteria (60) and of standardized diagnostic interviews, emphasis was placed on the development of operational diagnostic criteria. This was embodied in the DSM-III (61) and its successors, and in the clinical and research versions of ICD-10 (62,63). Studies of the reliability of child psychiatric diagnoses have been conducted with various schemes and instruments, giving rise to broadly similar overall conclusions (59).

Diagnostic reliability involves three rather different potential sources of error or variability: *information* variation (how data are collected); *interpretation* variance (how data are weighted and put together); and *criterion* variance (how algorithms are used to produce diagnoses). The first may be examined through test–retest studies to examine the extent to which the same answers are obtained on two consecutive occasions. On the whole, the findings have been of moderate to good reliability that is higher for symptom dimensions than for categorical diagnoses (64). This is affected, however, by the tendency for informants to report less psychopathology on the second occasion (64,65). This is more pronounced with highly structured interviews but can be reduced somewhat by attention to both details of wording of questions and interview organization (66).

Interpretation variance can be assessed by determining the extent to which two informants agree (see above), or two investigators concur in their ratings of behavioral descriptions (67,68), or two different diagnostic instruments provide the same answer. Typically this form of variance is greater—particularly across informant and across instruments. *Criterion* variance needs to be evaluated by comparing different ways of putting the data together. Standardization aims to keep this to a minimum but it is clear that different systems often give different answers (e.g., the findings with respect to age of onset in ADHD (69), number of symptoms in antisocial diagnoses (70) or diagnostic algorithms in autism (71)).

Diagnostic validity concerns the extent to which a diagnostic construct truly reflects a syndrome that is different from others. The testing of validity, therefore, requires research that examines correlates of diagnosis with respect to basic features that are external to the behaviors that define the hypothesized diagnostic construct (72). Such correlates might include genetic influences, neuropathology, biologic indices, course, and response to specific treatments. From a measurement perspective, validity concerns the extent to which empirical measures tap the crucial features that provide the basis of the diagnostic construct—that is, the vertical

connections between the top level (latent construct) and the bottom level (empirical measures) in Figure 3.2.1.4. The main measurement issue concerns the possible operation of biases in those vertical connections, expressed as Vn in Figure 3.2.1.4.

The main, possibly biasing, factor considered up to now has been the mental state of the informant (e.g., a depressed mother might overreport psychopathology in her child). To test that possibility it is necessary to determine whether maternal depression alters the pattern of associations between maternal reports of child psychopathology and teacher or child reports (73). The key statistic here relates to pattern differences and not to correlations as such. Thus, with respect to maternal depression the issue is whether a difference in child psychopathology is found on maternal reports that is not evident on reports from others. If there is, a bias is suggested. The weight of evidence from a range of studies indicates that there is some biasing effect, although not a great one. Recently, attention has broadened to consider whether depression in one parent alters the rating of the *other* parent by virtue of its influence on the overall family context (74). A comparable rating bias concern was raised with respect to possible *contrast* effects in parental ratings of twins. Thus, it was hypothesized that parents, in their ratings, might exaggerate differences between dizygotic (nonidentical) twins. Again, the test involves pattern effects in relation to the others. Such contrast effect biases have been found with respect to parental ratings of hyperactivity but, interestingly, not of other forms of disruptive behavior (75). Other examples of such possible rating biases concern the effects of a person's current social situation and mental state on their retrospective rating of negative childhood experiences (76). Findings suggest that there is a slight tendency for people who are doing well to *under* report past adversities but no tendency for people who are not doing well to *overreport* (an illustration of recall bias). Obviously, to test this possibility, it is necessary to have longitudinal data involving contemporaneous measurement of the adverse experiences. Yet another example concerns the possibility that people with a mental disorder may overreport comparable disorders in relatives (77,78). In all these examples the tests have involved some form of pattern difference that involves comparisons among different informants. Usually, the biases found have been small, but equally they have not been zero. The implication is that investigators need to use multiple informants and need to test for such possible biases, statistically correcting for them when required.

Latent Measurement Models

Historically, researchers tended to deal with these measurement problems either by choosing what seemed to be the "best" informant or alternatively by combining the ratings in some way (such as by adding them together or counting a report of a behavior if it comes from just one of a number of informants). Such composite strategies have the advantage of simplicity and, for this reason, they continue to have a worthwhile place in research. However, they fail to make use of all the data, they

do not deal quantitatively with possible biases, and they do not remove random measurement error. Latent variable models were developed to deal with these issues (see Fergusson (79,80) for clear descriptions of the rationale and the assumptions involved). In brief, multivariate statistics are used to *infer* the latent construct (which can be either dimensional or categorical) that underlies the associations among a variety of behavioral measures. The focus is on the variance that is *shared* across measures—in effect putting to one side the variance component which is unique to just one measure on the ground that, whatever its intrinsic importance, it is not measuring that which is common across measures. This "special" component is not thrown away but it can be isolated and examined in its own right. Latent variable methods also take into account prior probabilities and assessments in evaluating measurement error. Applications of latent construct measures in child psychiatry include studies of the impact of maternal depression on ratings of child psychopathology (81,82), the cross-informant correlations of behavioral reports (83,84), or the adult outcomes of antisocial behavior (85).

Impairment

The importance of including impaired functioning in case definition was well shown in Bird et al.'s (26) general population epidemiologic study. The prevalence of psychiatric disorder was 50% if assessed on the basis of symptoms and diagnoses alone, without taking account of impairment, but 18% if the latter was required for case definition (26). Similar results have been found in other studies (34,38,39,86).

The need to assess functional impairment is now generally accepted but it has proved difficult to define and measure in a valid fashion. Impairment is related to concepts of role performance that reflect individual's adaptation into his social environment (87). This must be related to developmental level and sociocultural context. Typically, impairment resulting from psychopathology is assessed in four domains: interpersonal relationships, academic/work performance, social and leisure activities, and ability to enjoy and obtain satisfaction from life. These need to be evaluated with respect to functioning at home, school, and in the community.

In earlier epidemiologic surveys (88) and in most classification schemes (62,89), the assessment of impairment was left largely to a global clinical judgment by the interviewer. In the early 1980s, instruments were developed to address this issue with the development of the Children's Global Assessment Scale (90). This instrument was shown to have adequate psychometric properties but it still relied on an experienced clinician, and did not specify how impairment data should be obtained. Further developments of this scale led to a simplified nonclinician version (87,91). Another instrument, the Columbia Impairment Scale (92), was devised to be completed by both parent and adolescent respondents; it has the advantage of being brief and providing scores for specific domains. Preliminary data suggest that it is a useful measure, with the parent CIS having consistently better validity than the

children's version. Other instruments exist, such as the Social Adjustment Inventory for Children and Adolescents (93) and the Child and Adolescent Functional Assessment Scale (87).

The issues to be addressed still include: (1) the differentiation between impairment and psychiatric symptoms (e.g., aggression to peers is both a symptom of conduct disorder and a reflection of impaired functioning with respect of peer relationships); (2) how to determine causal connections between symptoms and impairment (preliminary findings suggest that informants found this difficult (87) and interrater agreement was low (94)); (3) the difference between impairment and symptom severity; and (4) how to partition and attribute impairment in the case of comorbid presentations. Pickles et al. (95) found that depressive symptoms predicted later depression equally well with and without the presence of impairment; by contrast, the predictive power of conduct symptoms was increased in the presence of impairment. Angold et al. (96) found, in a community study, that over a fifth of children showed impairment even though their number of symptoms fell below specified cutoffs for diagnosis. These impaired children with subthreshold disorders were likely later to be referred to services, especially to school services in one study (39). Conversely, disorders without impairment tended to have a good outcome (97). The findings from the Ontario study tell much the same story (94).

Diagnostic interviews now include separate measures of impairment associated with disorders and symptoms (98,99). However, research is still needed on the origins of impairment; it cannot be presupposed that they will necessarily be the same as for symptoms.

CASE IDENTIFICATION AND SCREENING

Case Identification

Once a case definition has been established, case identification methods are selected. Adequate sampling techniques are required to provide unbiased estimates of rates and risk factors associated with disorders. Drawing of a sample requires the availability of a sampling frame and of sampling units covering the population of interest. In child psychiatry, surveys have often relied upon school rosters (e.g., Fombonne (11)) because, with compulsory education, they provide comprehensive sampling frames. Alternatively, households may be used as sampling units (e.g., Bird et al. (26); Ford et al. (37)). These approaches will still miss some children, such as homeless or street children (see Bird (26)) or those from families who migrate seasonally for employment reasons. Children in long-term residential facilities may also be overlooked. These losses will bias the findings if psychosocial factors associated with these unusual living circumstances are also risk factors for psychiatric disorders. Other sampling issues were discussed earlier.

Samples used in psychiatric surveys are often large, and direct interviewing of all study participants is not always convenient or possible. The two-phase design used in the Isle of Wight survey (88) has been frequently employed to deal with this difficulty. It requires a first phase of screening of all subjects with questionnaires easy to administer, followed by a diagnostic confirmation phase, more labor intensive, on a subsample of participants selected according to their results at the screening phase. The importance of understanding how screening instruments operate and how to measure their properties cannot therefore be overlooked.

Screening: Sensitivity, Specificity, Predictive Values

Dimensional measurements (whether by questionnaire or interview) lead to total scores ranging from a minimum (usually implying normality) to a maximum (mostly implying psychopathology). For both clinical and research reasons, investigators may want to transform these scores into categories (e.g., inferred normality vs. inferred disorder). Figure 3.2.1.5 depicts a fairly common situation in which scores among normal (noncases) are plotted next to those with a disorder (cases) and show a degree of overlap. Any cutoff will partition these two distributions into four groups, designated false and true positives and false and true negatives. All cutoffs (obtained by moving the vertical line C to the right or to the left in Figure 3.2.1.5) would of course result in some degree of misclassification. The measurement question concerns the determination of what score provides the best discrimination between cases and noncases and how the screening instrument performs in general. In practice, a cutoff has often been chosen before going to the field, and the results of the screening phase of an epidemiologic survey would lead to a tabular presentation as illustrated in Table 3.2.1.3. Various important indices can be used to summarize the data in this situation, including specificity, sensitivity, and positive predictive value. Sensitivity and specificity are two important proportions that are often quoted to summarize the properties of an instrument. Investigators wish both of them to be high, but as is obvious from Table 3.2.1.3 and Figure 3.2.1.5, they vary in opposite directions.

Estimating Prevalence from Screening Data

One consequence of the imperfection of our screening instruments is that the prevalence of a disorder cannot be directly estimated from the screening data of a survey. Unfortunately, some authors sometimes report the "prevalence" of a condition to be equivalent to the proportion of subjects who scored above the cutoff during the screening phase (the prevalence of eating disorders or that of depression has often been reported as the proportion of subjects scoring high on eating or depression inventories). This approach is wrong as the proportion of screened positives in a survey is made of the sum of true positives and false positives (a + b/N in Table

3.2.1.3), which is very different from the prevalence rate that corresponds to the sum of true positives and false negatives (a + c/N in Table 3.2.1.3). To take a practical example, assuming that a near-perfect screening instrument is available with a sensitivity and specificity of 90%, the results of the hypothetical screening of 1,000 individuals are shown in Table 3.2.1.4 under two separate hypotheses regarding the true population prevalence rate. In both examples, the prevalence rate is different than the proportion of screened positives and, in the case of a low prevalence rate of 0.01 (Table 3.2.1.4A), the proportion of screen positives (10.8%) overestimates the prevalence by a factor greater than 10. Thus, the results of any screening test administered in a population cannot be directly interpreted in terms of prevalence, unless sensitivity and specificity are known for this survey and taken into account in a more complex estimating function.
FIGURE 3.2.1.5. Distribution of scores in normals and cases.

TABLE 3.2.1.3

TYPICAL RESULTS OF A SCREENING EXERCISE

	Cases D	Normal $\bar{D}$	
Test positive: T+	a	b	a + b
Test negative: T−	c	d	c + d
	a + c	b + d	a + b + c + d = N

True positives: TP = a False negatives: FN = c D = diseased
False positives: FP = b True negatives: TN = d D− = nondiseased
Sensitivity (or rate of true positives: RTP): Se = a/a + c = p(T + /D)
Specificity (or rate of true negatives: RTN): Sp = d/b + d = p(T − / D−)
Rate of false negatives: RFN = c/a + c = p(T − /D)
Rate of false positives: RFP = b/b + d = p(T + / D−)

Prevalence: P = a + c/N = p(D)
Positive predictive value: PPV = a/a + b = p(D/T+)
Negative predictive value: NPV = d/c + d = p(D⁻ / T⁻)

Screening At-Risk Individuals

Another implication of the lack of perfect measurements has to do with screening particular individuals for the disorder of interest. If screening was perfect, we could infer in an individual with a positive screening score that he has the disorder; furthermore, we would expect that all individuals with the disorder would be picked up by the screening instrument. This ideal (but unrealistic) situation would correspond to a sensitivity and specificity of the screening tool of 100% (b and c would be equal to 0 in Table 3.2.1.3). As shown in the practical example of Table 3.2.1.4, the probability of detecting a disorder in a screened positive individual is in fact variable, and disappointing in the case of a low prevalence rate (Table 3.2.1.4A). This is despite using an instrument with excellent performance in terms of its sensitivity and specificity (both set at 90%). When the prevalence is low, cases in the screen-positive group remain too few in comparison to false positives, making inferences about the presence of the disorder in a screen-positive individual child too hazardous to draw. The situation is much different when the prevalence is higher (Table 3.2.1.4B). Illustrations of this issue abundant in child psychiatry. For example, in initial studies of screening questionnaires (for suicidality, eating disorders, etc.), excellent performances are often reported in differentiating cases and controls. However, the validation samples typically contain roughly equal proportions of cases and controls (which amounts to an artificial study population with a prevalence near 50%); when used later in more representative samples (where the prevalence is much lower), the questionnaire performances drop precipitously (100). A corollary message is that properties of an instrument are context-specific and *not* inherent qualities of the instrument. Sensitivity, specificity, and positive predictive value are empirical, tangible indices of the validity of a measuring instrument. The example shows that some of these properties can be affected by the context of their application (the prevalence) and that validity is not an intrinsic, absolute, instrument property. Rather, validity must be (re)evaluated according to the goals and context of a study and validity assessment is best viewed as an ongoing process.

Receiving Operating Characteristics Analysis

A scale or questionnaire is generally presented with one suggested cutoff point apparently associated with optimal performances (sensitivity and specificity). It is obvious that, as we move the cutoff point along the scale values, we would obtain different pairs of values for sensitivity and specificity. The investigator may want to vary the cutoff of an instrument to maximize sensitivity or specificity, depending on

their study goals, the consequences of misclassification (sometimes, it is highly desirable to limit the false-positive rate [increase the specificity] even at the expense of sensitivity, as in some biologic or genetic studies), or on the prevalence of the disorder. The receiving operating characteristics (ROC) curve simply plots sensitivity on one axis of a graph and the false-positive rate (1 – specificity) on the other for all possible cut points on a scale (see Figure 3.2.1.6). An ROC curve close to the diagonal corresponds to a poorly discriminant instrument, whereas the discriminant power of the instrument increases the farther on the upper left the ROC curve deviates from the diagonal. The area under the curve (AUC) is used as an overall summary index of the discriminant power of the scale. AUCs can be statistically compared to gauge the screening properties of different instruments, or to evaluate the gains or losses of discriminant power of a given tool when scoring instructions are changed, or items added or subtracted from the questionnaire. ROC analyses can also take into account the effect of the prevalence of the disorder on determining a best cutoff and evaluating the overall performance of an instrument, of the severity of cases under detection, and of the consequences of all types of misclassification errors (101,102). ROC analyses have been helpful in promoting a flexible use of instruments that can suit better investigators' needs in their research contexts.

TABLE 3.2.1.4

TWO SCREENING EXAMPLES

A: Prevalence of 0.01				B: Prevalence of 0.30			
	Cases	Noncases			Cases	Noncases	
Screen +	9	99	108	Screen +	270	70	340
Screen –	1	891	892	Screen –	30	630	660
	10	990	1,000		300	700	1,000
P = 0.01	Sp = 0.90			P = 0.30	Sp = 0.90		
Se = 0.90	PPV = 9/108 = 0.083			Se = 0.90	PPV = 270/340 = 0.794		

P, prevalence; Sp, specificity; Se, sensitivity; PPV, positive predictive value.
FIGURE 3.2.1.6. Receiving operating characteristics (ROC) curve.

Major Psychiatric Surveys

It is outside the scope of this chapter to review the substantive findings of child psychiatry epidemiologic surveys. Data on the incidence or prevalence of individual psychiatric disorders can be found in other chapters. In this section, we concentrate on current figures for overall psychiatric morbidity attributable to the most common internalizing and externalizing disorders.

Psychiatric Morbidity among Children and Adolescents. Epidemiologic surveys to assess prevalence usually rely on cross-sectional methods. Numerous prevalence surveys have now been conducted across the world (see Verhulst and Koot (40),

Canino et al. (103), Bird (86), Roberts et al. (104)). Table 3.2.1.1 presents the main results of recent surveys. The overall rates of psychiatric disorders underscore the most important finding. Psychopathology in young people is common, most studies estimating the prevalence to be between 10% and 20%. Verhulst and Koot (40) reviewed 49 surveys and computed an average rate of 12.9%. Emotional disturbances and disorders of disruptive behavior are equally common (with rates of 6% to 8%). It should be noted that many of these surveys will not have included neurodevelopmental disorders such as intellectual disability, language and other specific developmental disorders or autism and may not have picked up psychotic, bipolar, or eating disorders with an onset in late adolescence.

Community samples have also shown that only a small proportion (typically between 10% and 30%) of children with a disorder have had contact with specialist mental health services (25,37,105–107). Disorders involving disruptive behavior (37,108), and those that are severe or of long duration (109) are more likely to get referred. However, contextual factors (such as parental psychopathology) and family features also influence referral (110). The findings therefore indicate the need for caution in extrapolating from clinical samples or experience. Children seen in clinics often differ in systematic ways from nonreferred children with comparable levels of psychopathology. Epidemiologic findings are needed for the development of psychopathologic models.

Age of Onset. Age of onset is a definitional feature of several disorders. In ICD-10 (and DSM-IV), enuresis cannot be diagnosed before the age of 5, ADHD symptoms must be present before age 7, and Asperger syndrome is differentiated from high-functioning autism by the absence of a significant language delay by age 3. Age of onset is usually assessed retrospectively. However, the interrater and retest reliabilities of age of onset have been found to be poor outside the last 3 months for disorders with a recent onset and outside 1 year for those with a longer duration (111). Imperfect measurement of onset and offset of disorder can therefore influence prevalence estimates that are contingent upon specific time periods.

Age of onset also indexes differential outcomes. Moffitt (112) found that conduct disorders with an adolescent onset differed from early-onset conduct problems, with the latter more likely to be associated with neuropsychological impairments and with a worse long-term outlook. Similarly, adolescent-onset depression is associated with a particularly strong risk of recurrence in adult life (113,114), whereas the course and correlates of depression beginning before puberty is rather different (115–117). The timing of onset is also crucial in order to explore the direction of causal effects in patterns of comorbidity. The demonstration that ADHD is a risk factor for later conduct disorder (but that the reverse does not apply) (118,119) and that dysthymic disorder is a gateway to major depressive disorders (120) provide examples of this issue. Retrospective assessment of age of onset is also an issue in adult studies

(121), particularly as accurate assessment of this variable can influence results from familial studies (122) and from studies of secular trends (123). One way to avoid the problem of unreliability in the timing of onsets is to use lifetime prevalence estimates (e.g., Lewinsohn et al. (31)). These have the advantage of avoiding the problem of unreliability in the timing of onset and are probably the best approach for disorders present at the time of assessments. However, doubts arise over the reliability and validity of reports of past disorders that are no longer present. Such doubts probably apply less to disorders in childhood than in adult life because time spans are shorter and because multiple informants are available.

Risk Factors. A detailed review of risk factors for child psychiatric disorders identified in epidemiologic studies is out of the scope of this chapter (see chapters on individual disorders). Nevertheless, multiple risk mechanisms are now solidly established for specific disorders that have led to the development and systematic testing of treatments targeting these risk factors and to the consolidation of evidence-based practices. For example, the relationship between parenting problems, lack of maternal warmth, harsh discipline, marital discord, and the onset of antisocial symptoms in children has subsequently led to effective parent–child interventions (124). For many disorders, risk factors have been identified within the child (prenatal exposures, low birth weight, developmental delays, medical and especially brain disorders, IQ, cognitive style), in the family (parental psychopathology, marital discord, maternal sensitivity and warmth), in the school (classroom size, peer relationships, discipline practices, teaching styles), in the community (poverty, crime rates, access to drugs), and in broader societal factors (media viewing, body ideals).

There have been recent exciting developments in the systematic testing of causal mechanisms in child psychiatry epidemiology. Two are worth mentioning. First, the need is not only to identify a long collection of individual risk factors associated with psychiatric disorders but to develop models of psychopathology by examining the joint contribution of several risk factors operating in different domains (biologic *and* psychological *and* social) and in the course of individual development. Thus, the first examples of the importance of gene and environmental interactions were found in a cohort study where young adults homozygous for the short allele of the serotonin transporter gene were found to be at much increased risk of depression when (and only when) exposed to negative life events as compared to those individuals homozygous for the long allele (125). The findings clearly indicated that psychosocial risk factors operate differently in individuals according to their genetic background. The simultaneous study of risk factors is necessary to refine our understanding of child psychopathology and move beyond the frequent oversimplified explanations that are in use in clinical settings (the patient *is* depressed *because* something bad happened to her). The key point, though, is that carefully selected epidemiologic samples and measures, adequate sample sizes, and longitudinal

designs are necessary to fully evaluate these complex explanatory models. Second, new techniques of analyses of complex longitudinal data (trajectory methods) have shifted the focus from classical group-based predictor–outcome relationships to the identification of patterns of individual trajectories. Predictors of trajectory membership can then be identified, such as in the studies by Tremblay et al. (126) on the persistence or desistance of aggression over time. These methods are particularly suitable to the lifespan study of psychopathology and to a focus on individual differences in the onset and offset of psychopathologic conditions.

Comorbidity. The high frequency of cooccurrence of two supposedly separate forms of psychopathology was noted in the Isle of Wight studies over 50 years ago (88). However, it is only in the last 25 years that it has received much conceptual attention and empirical study (47,51,127–130). In their thorough review of the topic, Angold et al. (47) concluded that artifacts cannot account entirely for the frequency and patterns of comorbidity and that mechanisms underlying comorbid presentations should be studied more systematically, preferably with epidemiologic samples. Several research findings show how comorbidity may carry meaning. For example, the results of a family study of depression changed once comorbidity in the probands was properly taken into account (131) and a trend emerged for a positive drug response to tricyclic antidepressants in noncomorbid depressed subjects when results from a clinical trial were stratified according to the presence or absence of comorbid conduct disorder (132).

However, in order to undertake research using comorbidity it is necessary that the epidemiologic studies' methods of measurement are adequate for dealing with the assessment of psychopathology that involves comorbid patterns.

Special Topics

Preschool Studies. Epidemiologic investigations of preschool samples have been surprisingly few (133–139, 140). Nevertheless, studies have shown that psychiatric disorders starting in the preschool years show a high degree of persistence over time and that their course is systematically associated with identifiable risk and protective factors. For example, a difficult temperament in the child interacts with characteristics of family dysfunction to increase the risk of psychopathology 5 years later (141); and a shy, inhibited style of interaction predicts later onset of anxiety disorders in childhood (142). Furthermore, evidence has accumulated that developmental disorders usually identified in the early years have short- (143) and long-term consequences (144) with respect to psychosocial disturbances and functioning. Long-term follow-up of birth cohorts have also shown continuities between preschool behavior and adult psychopathology (145). Thus, identification of preschool problems is important, especially since early intervention might be more effective in the case of some disorders (146).

There are, however, particular challenges in the assessment of preschoolers (147). Infants and toddlers present with disturbances that tend to be closely associated with somatic development. Thus, feeding and sleeping difficulties are common in this age group. It is also an age when the effects of prenatal/perinatal risk factors may be particularly marked. Second, infants' behavior is closely intertwined with interactions with their caregivers. Accordingly, it is necessary to consider the extent to which any disturbance reflects psychopathology in the child rather than difficulties in a dyadic relationship. Third, specific developmental delays such as language or social relationships are first evident in the preschool years and call for a multifaceted developmental assessment. Fourth, very few dimensional measures assessing behavioral/emotional deviance have been properly validated for children below the age of 4. Finally, current diagnostic schemes have acknowledged limitations for use with very young children (148). Scales such as the Temperament and Atypical Behavior Scale (149) and classifications such as the Zero-to-Three diagnostic classification (150) have been developed for infants and toddlers but they are based on particular conceptual frameworks and are closely linked to intervention strategies. However, downward extensions of psychiatric interviews have been recently developed and tested in preschoolers and have shown good psychometric properties (151). The use of this new generation of instruments in population-based samples of preschool children indicates that both rates and patterns of disorders and comorbidity in preschool samples are comparable to those of older children (152).

Norm-Referenced Instruments. Reference to normative data is implicit in the assessment of psychopathology. However, it was only in the late 1950s that systematic surveys of children's behaviors and emotions were undertaken on large samples of nonreferred children (22). The epidemiologic surveys of child psychiatric disorders that followed helped to promote knowledge of normative behavior at different ages with the useful development of standardized questionnaires for use with multiple informants (40,41,88,153). Increasingly, data from large representative samples of nonreferred children have been used to calibrate measures in order to provide the best identification of probable psychopathology. However, not all standardizations have used fully representative general population samples. There must be reservations about generalizability when convenience samples have been used. Second, norms are derived from particular regional or national samples and the query is whether it is justifiable to extrapolate to other regions or countries. For example, a 10- to 15-point difference in mean CBCL total scores has been reported among American, Australian (154), French (155), and Puerto Rican children (156). The question is whether these differences reflect true regional differences in psychopathology or rating tendencies that have been influenced by cultural contextual features. Both possibilities have to be considered seriously, but their differentiation requires the use of external validators of some kind. The Isle of Wight–Inner London

comparison indicated that a true difference in rate of psychopathology was likely (157), whereas the United Kingdom–Hong Kong comparison with respect to hyperactivity suggested a rating difference effect (158). Investigators are well advised to be cautious about assumptions that one set of norms can be generalized to different populations.

Similar issues concern extrapolations from one large representative population to subgroups within. For example, are associations between social class and behavioral disturbance (41,42) a true reflection of valid differences or a contextual rating bias effect? The same applies to age and gender differences. An automatic assumption that subgroup norms should be used or that any differences from total population norms are necessarily valid should be resisted. As ever, external validation is essential.

Third, norms apply to one particular point in time. Evidence has accumulated that there have been secular changes in the incidence of various psychosocial disorders (159–161) and of individual behavioral problems. Thus, Achenbach and Howell (162) compared two large representative samples of American youth surveyed 13 years apart and found increased scores on 46 of 118 behavioral problems and on all scale scores (the mean total score increasing from 18 to 24.2) in the most recent birth cohorts. Periodic recalibration of instruments is necessary in child psychopathology, just as it is for other measures such as psychometric tests (163,164) or physical indices such as height, weight, head circumference, and pubertal maturation (165).

Cultural Issues. Most industrialized societies today are multicultural, multiethnic, and multilingual, a fact that has important implications for clinical practice. In addition, it has consequences for the assessment of psychopathology by means of standardized interviews or questionnaires. It would be a mistake to exaggerate the methodologic difficulties. Rating scales have usually been found to function in much the same way across cultures (166–169) with, for example, comparable gender differences (154,155,169).

Nevertheless, three issues require attention. First, there is a concern to ensure linguistic equivalence. This is usually accomplished by a series of back translations from one language to the other by independent bilingual translators who are familiar with the psychopathologic concepts. The last specification is important to ensure that the appropriate words are selected to tap the intended meaning. That is relevant, too, in relation to the need to ensure equivalence between American and British versions of instruments. The problems of going across languages are even greater and it is crucial that the translators appreciate the intended meaning in relation to psychopathology. Issues in relation to the translation of diagnostic interviews for Hispanics were described by Canino and Bravo (170) and examples of translation inaccuracies and of their effects on deviance scores were noted by Woodward et al. (171).

Second, there is the question of conceptual and perceptual equivalence. Thus,

Weisz et al. (172) reported differences between Thai and American adults in their concern over particular behaviors; Lee (173) queried whether a morbid fear of fatness had the same implications for anorexia nervosa in Hong Kong as it does in Western societies; and King and Bhugra (174) posed the same question with respect to questions on dieting when used in cultures where this is part of religious practice. It cannot be claimed that there is an adequate knowledge base to show either the importance of these concerns or how they are best dealt with, but investigators need to be alert to their possible effects on measurement. They are likely to have effects because most ratings involve an explicit or implicit comparison with some norms, the behaviors being normal at a low level but abnormal at some higher level.

Third, there is the question of diagnostic equivalence. Some cultures have syndromes that appear to have no obvious equivalent in other cultures, although systematic evidence on this is largely lacking. From a measurement perspective, perhaps the key point is that when different cultures express the same disorder through differently expressed manifestations, there needs to be caution in the application of diagnostic algorithms. For example, there is evidence that cultures vary in the extent to which they express depression in reports of feelings of misery; some are more likely to report these in terms of somatic complaints (175). Similar issues arise with respect to age variations, as reflected in the different role given to irritability in the diagnosis of depression in childhood and in adult life (89). Once more, there is at least as much of a danger of wrongly assuming an age (or cultural) difference as of overlooking a real difference. The arbitration has to lie in empirical studies. Recent systematic comparisons of children's emotional and behavioral problems assessed in over 30 cultures with the same instruments indicate that cultural differences are relatively small across countries, with mean scores for most samples falling close to the omnicultural mean (176,177).

Language of Assessment. Practically, as population samples in most countries reflect a mixture of cultures and languages, it has become essential for epidemiologists but also for clinicians to have access to instruments adequately translated and validated in different languages. The common instruments used to evaluate general psychopathology in children and adolescents are available in multiple languages. For example, access to non-English versions is obtained through specific websites associated to the corresponding instruments, for example, http://www.aseba.org/ordering/translations.html for the 90 international versions of the Child Behavior Checklist and http://www.sdqinfo.com/b3.html for the 86 translations of the Strengths and Difficulties Questionnaire. Translated versions of various instruments tapping specific dimensions of child psychopathology also exist and are available either from their authors or commercial distributors. Non-English versions of various diagnostic interviews also exist in different languages, although the work is less advanced than that for general psychopathologic rating scales. It is

prudent to check with the original authors of an instrument whether or not an available translation has been approved by them and properly established.

Studying Transitions to Adulthood. With a growing emphasis on lifespan perspectives on developmental psychopathology and an increasing focus on the study of continuities and discontinuities between child and adult disorders, psychiatric epidemiologists have now developed adult versions of child instruments that are suitable for longitudinal research and provide investigators with measurements that are highly consistent across age groups. For example, adolescent samples evaluated with a combination of the Child Behavior Checklist and Youth Self-Report Form can be followed as young adults with parallel adult versions of these instruments such as the Adult Self-Report and the Adult Behavior Checklist that can be used up to age 59. Versions for subjects aged 60 or older are also available (http://www.aseba.org). Similarly, adult extensions of child psychiatric interviews such as the CAPA or the DISC are being developed.

Interviewing and Computer Technology. Modern technology has allowed many assessment procedures to be computerized. For example, Berg et al. (178) compared the reliability, concurrent and criterion validity of two standard and computer-assisted procedures to collect data using two common psychopathology scales, the Rutter A2 scale and the CBCL. Psychometric properties were similar with the two procedures, suggesting that computer-assisted technologies might be used more extensively in routine practice.

There are numerous advantages to computerization: It eliminates observer bias; it ensures that all respondents receive precisely the same instructions and questions; by having a voice read the questions aloud it circumvents illiteracy problems; it allows more complex and flexible skip and branching patterns than possible with paper and pencil procedures; it makes immediate checking of the consistency and range of responses possible; and it provides error-free computation of scores with or without reference to existing norms. Data are stored readily in a format that allows for further analysis; computer storage also makes the data collection procedure less vulnerable to errors such as accidental loss of data, theft, or inadvertent disclosure of confidential materials.

Several structured diagnostic interviews already have computerized versions. The role of the computer does, however, vary considerably. Computers are sometimes used to assist interviewers in their task of conducting the interview. In this instance, the interviewer still performs a face-to-face interview and records the answers of the respondent on a laptop computer as the interview proceeds. This procedure has both the advantage and disadvantage of allowing some degree of interviewer judgment. Fully computerized diagnostic interviews tend to be highly structured, with restricted response options. Computer-aided administration is particularly useful in helping the interviewer to follow complex skip rules and to track respondent's answers that

require follow-up questions in the course of the interview. The NIMH DISC-IV (98) is typical of such interviews devised for large-scale epidemiologic surveys. The DAWBA (179), used in the U.K. National Survey of Child Mental Health (37), provides another example, with the additional feature that space is allocated to record respondents' descriptions verbatim as well, so allowing a subsequent overarching clinical interpretation of all structured data and of open-ended commentaries. This procedure, however, detracts somewhat from the greater efficiency of the computerized interviews—a major selling point. In other developments, computers are used to replace interviewers fully. Some sound versions of diagnostic interviews have now been developed for full self-administration, using headphones or speakers. The Voice DISC (98) and a substance abuse module of the CAPA (99) are examples of such developments, which totally eliminate interviewer costs.

Investigator-based interviews have been, for obvious reasons, less amenable to computerization, although some attempts have been made, such as with the DICA (180). One diagnostic interview relying on displays of pictures or cartoons to elicit symptomatic data has been released in computerized form (Interactive Dominic Questionnaire (181)), but more data are still needed on its basic properties.

Computerized interviewing does not usually decrease the time needed to administer the interview, but it can lead to substantial savings in terms of interviewer time (and costs) by eliminating that used for coding and interpretation. Successful use has been achieved in recent epidemiologic surveys (37,182).

It is possible, too, that computerized interviews may be better at eliciting potentially embarrassing personal information, because it eliminates the interpersonal context. Reich et al. (183) found that children enjoyed the computerized DICA-R interview, preferred it over a person interview, and said that they would tell things to the computer that they would not tell to a person. Survey research has shown that rates of at-risk behaviors involving sexual contacts and use of addictive substances were three times higher when questions were asked via audio-computerized methods than when asked face to face (184). Similar results have been found regarding suicidal behaviors (e.g., Reich et al. (183)).

It is too early to draw firm conclusions on the merits and demerits of computerized interviews. Clearly, they have very important advantages for some purposes and there is no doubt that they will be used more in the future. However, for some purposes, their chief advantage of eliminating the need for interviewers may be a disadvantage, just because it eliminates personal contact. The structural format, too, will be limiting in relation to the eliciting of important unexpected information.

Computerized Clinical Databases. The progress made in the measurement of child psychopathology in epidemiologic research has been paralleled by similar advances in the systematic evaluation of patients referred to mental health teams. Multiaxial

diagnostic formulations and use of norm-referenced general psychopathology questionnaires are now standards in most clinical centers. Yet, despite the easy access to computers and databases, the data collected are usually not made readily available for research applications to clinical researchers (be they epidemiologists or clinicians). A good example of the usefulness of such clinical data recording systems is the Item Sheet that has been in place at the Maudsley Hospital for over half a century and which records diagnoses, symptoms, demographic details, psychosocial features, test findings, details of referral, and rating of clinical outcome. This large computerized database has allowed for the study of specific problem behaviors, sampling for long-term follow-up studies, patient comparisons between centers in different countries, the investigation of trends over time in specific behavioral problems and of their causes, and the study of comorbid patterns (113,160,161,185). More streamlined data recording systems could easily achieve the same goals if a core set of variables were defined. Also, centers could decide to add on, for specific groups of patients of interest, or for defined periods of time, more exhaustive data recording procedures, because databases can easily be managed on modularity principles. Progress in information technology has made it easy and cheap to set up such databases and to exchange data when appropriate. Indeed, the need to audit services and to be accountable with regard to services activity for the health service will make such systems increasingly mandatory in most countries. Timely recognition of these needs and of the usefulness of these databases will help mental health professionals to influence these information systems in a way that might be more clinically relevant and useful for their own research and practice.

CONCLUSION

Progresses in child psychiatric epidemiology have been impressive in the last 40 years and have been made possible by the development of empirical and replicable measurement approaches to children's maladaptive behaviors and psychiatric disorders. The impact of epidemiology has been on several areas. For clinical practice, epidemiology has provided normative data on child behavior that are necessary to evaluate problems seen in clinical settings. As physiology is needed in medicine to understand disease pathology, knowledge of typically developing children acquired through epidemiologic inquiries is needed for understanding child psychopathology.

Knowledge of the clinical significance of individual symptoms, of the risk factors associated with psychiatric disorders, of their population prevalence and incidence, is required for developing appropriate models of child psychopathology. For public health, surveys have drawn the attention on the importance of global morbidity in children due to mental health problems. In addition, disorders with an onset in childhood or adolescence have strong continuities with adult disorders, thus

contributing to the burden of mental illness across the lifespan. Unfortunately, and despite increasing availability of evidence-based practices with demonstrated efficacy in controlled studies, access to services is insufficient in most countries. At a time where several indicators have shown upward trends in rates of behavioral disturbances in young people, service planners and policymakers should be made aware of this discrepancy. Progress in understanding causal mechanisms underlying some disorders has been substantial. Several risk factors are now well established that could be targeted by treatment and prevention programs. More refined understanding of child psychopathology is emerging, with new studies that now incorporate a joint assessment of genetic, biologic, and psychosocial factors, and combine longitudinal and developmental approaches in genetically informative designs to test competing hypotheses on psychopathologic mechanisms.

[1]Technically, prevalence is a true proportion and not a rate (that implies different units of measurement for the numerator and denominator) although it is commonly referred to as a "rate," as we do later in the text.

CHAPTER 3.2.2 ■ HEALTH PROMOTION AND PREVENTION IN CHILD AND ADOLESCENT PSYCHIATRY

KERRY O'LOUGHLIN, ROBERT R. ALTHOFF, AND JAMES J. HUDZIAK

The perfect storm for positioning the field of child and adolescent psychiatry to the forefront of health care reform is upon us. If we embrace the power and scope of health promotion and illness prevention, our field will become central to the care and well-being of all children and families. Child and adolescent psychiatrists are the only physicians trained to understand the emotional and behavioral correlates of the structure and function of the developing brain. No other field combines classic medical training with an understanding of brain and behavior development from birth to age 24, the age span that defines the children and families we serve. Over the past two decades multiple domains in medical research have matured to the point that child and adolescent psychiatry is perfectly positioned to execute a paradigm shift in how our field is defined and practiced.

The change agents include rapid advances in the understanding of genetics (1), epigenetics (2), and structural (3) and functional (4) neuroimaging studies of large populations of children across development (5). This research allows our field to understand the unique vulnerabilities and opportunities that occur during the epoch of brain development. Second, with the explosion of interest and evidence from the multiple Adverse Childhood Experiences (ACEs) study, it is now clear that the same factors that place children at risk for anxiety, depression, and substance abuse also contribute to similarly elevated risk for obesity, diabetes, and hypertension (and many other general medical problems) (6). These data allow our field to rightly claim a special role in addressing and preventing the factors that precede the most common and costly of all medical illnesses, not just psychiatric illness. The third major advance exists in the area of health promotion. Cardiologists would never define themselves as physicians who only care for patients' with end-stage heart disease, rather cardiology is defined as a field that also has developed heart health promotion and illness prevention programs (e.g., through diet and exercise) (7). This has led the rest of medicine to appreciate the importance of promoting cardiac health in all humans. Child and adolescent psychiatry should and can follow that same method. Modern neuroscience has positioned child and adolescent psychiatrists to design brain healthy health promotion programs from pregnancy to adulthood. Next, epidemiologic research in the fields of psychiatry and child psychiatry has moved away from dependence on categorical models of diagnoses such as embodied by the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-5) (8) and into quantitative research diagnostic procedures. It has become increasingly obvious that all children (indeed all humans) experience symptoms of sadness, anxiety,

inattention, risk-taking, rule-breaking behavior, and quirkiness thus redefining the target populations for child and adolescent psychiatry away from serving only children who meet criteria for largely inadequate diagnoses to all children (9). In other words, all of us carry symptoms of emotional behavioral vulnerability and a new child psychiatry can devote itself to the service of all children. Finally, the era of family-based medical care is upon us. The realization that treating a child as if she/he exists in a vacuum is no longer tenable in our field or any other field in medicine. However, we can take the lead in developing new programmatic approaches. For almost as long as our field has existed the argument for family-based care has been made, however, with new research, we now have the evidence to confidently move the argument forward that the best way to help a child or adolescent achieve wellness is to help his or her family become well.

These advances, taken together, invite child and adolescent psychiatry to operate under the following coda: the environment influences genomic health, which in turn influences the structure and function of the brain, which in turn influences a child's thoughts, feelings, and behaviors. Given that all health begins with emotional behavioral health, the path to wellness begins with creating healthy environments for all children and families.

With this in mind child psychiatry can enter the epoch of accountable care and health care reform with the following charge: we must design, test, and implement health promotion programs aimed at building healthy brains from birth to adulthood. We must design, test, and implement illness prevention programs aimed at helping those at risk for developing psychopathologies and medical morbidities (that are very difficult to treat in adulthood). When we intervene we should do so in a family-based manner with the knowledge that the best way to serve a child is to serve a child's family. If child psychiatry accepts this charge, we essentially place ourselves at the center of health care reform. Our profession already contributes to the health and well-being of children in school settings, in pediatric and community settings, as well as in our clinics and hospitals. Armed with new evidence we can contribute strategies to promote health in all children, to prevent the development of illness in many, and to intervene in a more empirical and family-based way for those who struggle with emotional behavioral illness.

In this chapter we provide child and adolescent psychiatry with the evidence for illness prevention and health promotion, and provide one model of family-based intervention that is already in place in schools, pediatric settings, and clinics in the United States and abroad (9,10).

HISTORY OF PREVENTION

Over the last 50 years, the terminology surrounding prevention has undergone a number of revisions (11). In 1964, in an effort to establish a consistent nomenclature,

the field of psychiatry adopted a series of definitions to describe efforts toward prevention. In Caplan's *Principles of Prevention Psychiatry,* prevention was subdivided into three categories: primary prevention, secondary prevention, and tertiary prevention (12). Primary prevention was defined as "an intervention designed to decrease the number of new cases of a disorder or illness," secondary prevention was defined as "an intervention designed to lower the rate of established cases of a disorder or illness," and tertiary prevention was defined as "an intervention designed to decrease the amount of disability associated with an existing illness" (11).

In 1983, Gordon proposed a prevention classification system based on the costs and benefits of delivering an intervention to a targeted population (13,14). Gordon's taxonomy distinguished between universal prevention, selected prevention, and indicated prevention. In this framework, universal prevention referred to strategies for the entire population. Selective prevention referred to strategies that targeted a subpopulation deemed to be at risk for a disorder. Finally, indicated prevention referred to strategies that targeted *individuals* who were asymptomatic, but deemed, based on an individualized assessment, to be at increased risk (13).

In 1994, the Institute of Medicine (IOM) report *Reducing Risk for Mental Disorders: Frontiers for Preventive Intervention Research* established a continuum of care beginning with prevention, and including both treatment and maintenance (15). Prevention referred to interventions implemented prior to a patient receiving a diagnosis, treatment referred to interventions provided to individuals with diagnoses, and maintenance referred to long-term interventions designed to reduce rates of relapse and disability and to promote rehabilitation among individuals with chronic mental illness (11,14). Approximating the model proposed by Gordon (13), the 1994 IOM committee divided what was formally referred to as primary prevention into indicated, selective, and universal preventive interventions. In this model, distinction among indicated, selective, and universal preventive interventions was based on the population being targeted. Universal preventive interventions were designed to serve the entire population, selective preventive interventions were designed to serve individuals at heightened risk, and indicated preventative interventions were designed to serve populations manifesting early symptoms of a disorder (15). This conceptualization differed from Gordon's model as indicated preventive interventions targeted individuals with prodromal symptoms (rather than individuals who were at-risk, yet asymptomatic) (14). Within the context of such definitions, the IOM's 1994 report also proposed that as risk increased the intensity of the intervention and the costs associated with that intervention would also increase (16).

While the IOM model provides a useful framework for conceptualizing the nature and degree of risk faced by vulnerable populations, it is important to note that there is often significant overlap and interrelatedness among vulnerable populations (16). Indeed, individuals manifesting the early symptoms of psychopathology (i.e., an

indicated population), are often a subset of individuals at increased risk (i.e., a selective population). As such, the distinction between selective and indicated preventive interventions is often nebulous. Beyond the broad definitions provided by the IOM in 1994, there are no explicit criteria for whether a preventive intervention be classified as selective or indicated (16).

HEALTH PROMOTION

In 2009, the National Academy of Sciences (NAS) committee largely concurred with the continuum (i.e., including prevention, treatment, and maintenance) laid out in the IOM's 1994 report (14). However, the NAS report suggested that in addition to prevention, treatment, and maintenance, the conceptualization of mental health should be broadened to include the *promotion* of mental health. Citing the World Health Organization's (1986) proclamation that health is more than merely the absence of disease, the NAS committee defined mental, emotional, and behavioral health promotion as, "efforts to enhance individuals' ability to achieve developmentally appropriate tasks (developmental competence) and a positive sense of self-esteem, mastery, well-being, and social inclusion and to strengthen their ability to cope with adversity" (14,17). In the NAS report, health promotion was characterized as focusing on well-being rather than on the prevention of illness. While drawing this distinction, however, the report also highlighted the considerable overlap between prevention and health promotion, stating that: "both (prevention and health promotion) focus on changing common influences on the development of children and adolescents in order to aid them in functioning well in meeting life's tasks and challenges and remaining free of cognitive, emotional, and behavioral problems that would impair their functioning" (14).

Established Preventive Interventions

Both the IOM and NAS have acknowledged, on a conceptual level, the importance of prevention. However, research within child and adolescent psychiatry has lagged behind such conceptual advances. To date, there are a limited number of preventive interventions, and even fewer with a strong empirical base. Therefore, selecting an evidence-based preventive intervention can prove difficult for physicians, mental health care providers, communities, schools, and parents alike.

There are, however, a number of registries which evaluate and rank preventive interventions based on the strength of their empirical evidence. One such registry is the Blueprints for Healthy Youth Development Program (18). Funded by the Annie E. Casey Foundation, the Blueprints for Healthy Youth Development Program provides a freely available registry of evidence-based preventive interventions. Since its inception, the Blueprints program has reviewed more than 1,400 preventive

interventions. During this time, only 14% of programs have met the registry's minimum inclusion criteria, and less than 1% have been designated as "model" programs (18).

To be designated as a "model" program, a preventive intervention must have: (1) a minimum of either two high-quality randomized controlled trials or one high-quality randomized controlled trial and one high-quality quasiexperimental evaluation; (2) positive intervention impact sustained for 12 months after the program intervention ends; and (3) significant impact, intervention specificity, and dissemination readiness (19). To be a "model plus" program an intervention must meet the above model criteria and have undergone independent replication (19).

In the interest of providing an overview of the existent preventive interventions with the largest evidence base, each of the programs receiving the "model" or "model plus" designation from the Blueprints registry are briefly described below. Based on the definitions established in the IOM's 1994 report (15), the programs reviewed below have been categorized as: universal or selective/indicated preventive interventions.

Universal Preventive Interventions

The LifeSkills Training Program

The LifeSkills Training Program (LST) is a classroom-based program designed to prevent adolescents from engaging in alcohol use, drug use, and violent behavior (20). The LST is designed to teach students self-management skills, social skills, and drug-resistance skills, and has been associated with short- and long-term reductions in tobacco use, alcohol use, illicit substance use, polysubstance abuse, violence, and delinquency (20). In addition, at 6- and 10-year follow-up, the LST has been associated with reductions in risky driving (21), and HIV-risk behaviors (22).

The Positive Action Program

The Positive Action Program is a school-based program designed to enhance social–emotional learning and positive behavior in elementary and middle school students. The classroom component teaches self-management skills, as well as strategies to increase the use of positive social behavior (23). The Positive Action Program also includes a school-wide component designed to reinforce the classroom-level intervention (23). The Positive Action Program has been associated with reductions in suspensions and absenteeism; reductions in substance use, violence, and sexual activity; increased rates of socioemotional development; higher life satisfaction; reduced rates of depression and anxiety; reduced rates of unhealthy food consumption; as well as overall improvements in school quality (23,24).

The Promoting Alternative Thinking Strategies

The Promoting Alternative Thinking Strategies (PATHS) program is a school-based program designed to reduce aggression, and promote emotional and social competencies in children grades K-6 (25). The PATHS intervention targets five domains: self-control, emotional understanding, positive self-esteem, relationships, and interpersonal problem-solving skills (25). The PATHS intervention attempts to involve parents by incorporating home activity assignments and providing parents with information. PATHS has been associated with lower rates of conduct and externalizing behaviors, lower internalizing scores, better emotion recognition abilities, reductions in delinquency, and higher proficiency scores in reading, writing, and math (25–27).

Project Toward No Drug Abuse

Project Toward No Drug Abuse (TND) is a drug prevention program for high school students who are at risk for substance use and violent behaviors (28). Project TND is designed to enhance self-control, communication, resource acquisition, and decision-making. Project TND has been implemented as a universal preventive intervention in general populations, as well as a selective preventive intervention among high-risk students (28). Project TND has been associated with reductions in cigarette use, marijuana use, hard substance use, weapon carrying, and victimization, with reductions in hard drug use being sustained for up to 5 years post-intervention (29,30).

Selective and/or Indicated Preventive Interventions

Nurse-Family Partnership

The Nurse-Family Partnership (NFP) is a maternal health program which provides first-time low-income mothers with maternal and child health nurses (31). The intervention is designed to improve pregnancy outcomes, improve infant health, promote infant development, and improve the mother's life course trajectory (31). In particular, during pregnancy, the NFP is designed to eliminate cigarette, alcohol, and drug use and encourage rest, exercise, and sound personal hygiene habits (31,32). The NFP also aims to prepare mothers for labor, delivery, and child care (31). Among mothers, the NFP program has been associated with reductions in unintended pregnancies, domestic violence, and increased rates of employment (31,32). Among children, the NFP has been associated with reductions in hospitalization for injury and illness, accelerated language development, reduced rates of behavior problems at age 6, and reduced rates of arrests, internalizing disorders, and substance use at age 12 (33).

New Beginnings

The New Beginnings program is an intervention for divorced mothers with children ranging in age from 5 to 18 (34). The New Beginnings program is a parent-driven intervention designed to help mothers engage in effective child behavior management strategies, enhance the quality of mother–child interactions, and reduce children's exposure to interparental conflict (34). Among children, the Blueprints program has been associated with decreases in internalizing, externalizing (34,35), and aggressive behaviors (34,36). With respect to family dynamics, the New Beginnings intervention has been associated with improvements in the use of effective discipline strategies, parent–child communication, and positive routines (36).

Treatment Foster Care Oregon

Treatment Foster Care Oregon (TFCO) is a 6-month intervention for adolescents with a history of antisocial behavior, emotional disturbance, and delinquency (37). Foster families from the community are recruited and trained to provide adolescents with clear and consistent limits, appropriate consequences, and positive reinforcement for appropriate behavior (37). In so doing, the TFCO system also provides adolescents with a mentoring adult and separation from delinquent peers groups (37). The TFCO uses a behavior modification system where adolescents can accrue points for appropriate behavior, and over time gain increased levels of independence. The TFCO also includes individual and family therapy and emphasizes that adolescents develop interpersonal skills and participate in social and recreational activities (37). The TFCO program is associated with reductions in days spent incarcerated, reductions in tobacco and marijuana use, reductions in violent offenses (37), and among females, reductions in the odds of becoming pregnant (37,38).

Multisystemic Therapy

Multisystemic Therapy (MST) is a family- and community-based intervention designed to improve antisocial behavior patterns in adolescent juvenile offenders (39). MST works across multiple settings (i.e., in the home, school, and community) to increase prosocial behavior and decrease antisocial behavior. MST has been associated with decreased rates of rearrest, recidivism, incarceration, psychopathology, and substance use, as well as increased rates of community service (39,40).

Multisystemic Therapy-Problem Sexual Behavior

Similar to the broader MST intervention, the Multisystemic Therapy-Problem Sexual Behavior (MST-PSB) intervention focuses on the family, school, peer, and

community systems in which an adolescent is embedded in order to reduce antisocial behavior (41). However, MST-PSB focuses specifically on the dimensions of the youth's environment that are related to problematic sexual behavior. MST-PSB strives to increase each adolescent's friendships and age-appropriate sexual experiences, and works with adolescents to increase perspective taking abilities and maladaptive beliefs and attitudes, particularly around sexual offending (41). MST-PSB is associated with reductions in rearrests for sexual and nonsexual crimes (42), parent and child psychiatric symptoms, youth behavior problems, as well as improvements in peer relationships, family functioning, and academic performance (41,43).

The Blues Program

The Blues Program is a cognitive-behavioral group depression intervention designed for adolescents with prodromal symptoms of depression (44). The program aims to provide social support and help adolescents restructure maladaptive thinking, develop plans to respond to future stressors, and participate in pleasant activities (44). The Blues Program has been associated with reductions in depressive symptoms immediately following the intervention (45), 6 months post-intervention (46), and both 1 and 2 years post-intervention (44,47). Adolescents participating in the Blues program also report reductions in substance abuse immediately following the intervention and 6 months post-intervention (44,46).

The Body Project

The Body Project is a 4-week group intervention designed for high school and college-aged females with disordered eating. The Body Project engages participants in body acceptance exercises and teaches strategies to avoid peer pressure (48). Post-intervention, the Body Project is associated with decreases in thin ideal internalization, body dissatisfaction, negative affect, risk for obesity onset, symptoms of bulimia, and disordered eating (48,49). Many of these effects are maintained for 3 years (48).

Brief Alcohol Screening and Intervention for College Students

Brief Alcohol Screening and Intervention for College Students (BASICS) is a two-session intervention designed for individuals aged 18 to 24 who are at risk for alcohol use disorders (50). BASICS strives to help college-aged students better understand the risks associated with drinking, enhance motivation to change, develop skills to moderate drinking, and ultimately make better alcohol use–related decisions (50). College-aged students who participate in BASICS demonstrate reduced rates of drinking and problem behaviors at 2- and 4-year follow-ups (50,51). Among first-

year college students, BASICS has been associated with lower levels of peak blood alcohol concentration and reductions in the number of drinks consumed during the weekend (50).

Functional Family Therapy

Functional Family Therapy (FFT) is a family-based intervention for delinquent adolescents and their families (52). FFT is designed to enhance parenting skills, youth compliance, family communication and supportiveness, and decrease negativity and dysfunctional behavioral patterns (52). FFT is associated with reductions in recidivism, youth internalizing and externalizing symptoms, substance use, as well as enhanced family interactions (52,53).

Parent Management Training—Oregon Model

Parent Management Training—Oregon Model (PMTO) is a group-based parent training intervention for the parents of children ranging in age from early childhood to late adolescence (54). PMTO is designed to enhance effective family management skills and thereby reduce antisocial and problematic behavior in children (54). Research suggests that PMTO is associated with reductions in coercive parenting, noncompliance, and negative reinforcement, and increases in effective and positive parenting (54,55). Among children, PMTO is associated with reduced rates of Oppositional Defiant Disorder, aggression, internalizing disorders, and externalizing disorders (54,56,57). Nine years post-intervention, PMTO is associated with decreases in teacher-rated delinquency (54,58) and arrest rates (54,59).

A Summary of Existent Preventive Interventions

Irrespective of the population being targeted, the goal of preventive interventions is to reduce the influence of established causal risk factors, augment the availability and/or influence of known protective factors, and reduce the likelihood that children will develop (or progress toward) psychopathology.

Cutting across the many contexts (e.g., individual, peer, family, school, community) in which a given child or adolescent is embedded, and utilizing a variety of therapeutic modalities (e.g., school based, individual, group, family) the preventive interventions outlined above exert a significant influence on a variety of known risk and protective factors. Broadly speaking, these interventions can be broken down into those involving the child and those involving the family.

The child-based risk factors modified by the preventive interventions reviewed above include low school commitment, body image concerns, substance use, aggressive behavior, physical violence, poor academic performance, positive attitudes toward drug use, favorable attitudes toward antisocial behavior, and

interaction with antisocial peers (60). The child-based protective factors enhanced by the interventions reviewed above include coping skills, problem-solving skills, perceived risk of drug use, social interaction skills, prosocial involvement, interaction with prosocial peers, drug refusal skills, and academic self-efficacy (60).

The family-based risk factors modified by the programs reviewed above include family violence, parental mental health difficulties, poor family management, neglectful parenting, lack of prenatal care, household adults involved in antisocial behavior, low socioeconomic status, maternal substance use during pregnancy, parental unemployment, unplanned pregnancy, and parent stress (60). The family-based protective factors modified by the programs reviewed above include: clear standards for behavior, nonviolent discipline, attachment to parents, and parental social support (60). Thus, many of the most well-supported preventive interventions alter family-level risk and protective factors and thereby prevent illness and promote health in children and adolescents.

Established and Emerging Modalities for Prevention and Health Promotion

Clearly, at both the child and family level, preventive interventions have the capacity to shore up protective factors and reduce risk factors. Given the prominence of family-level variables in the preventive interventions outlined above, and given the known genetic and environmental contributions to every developmental psychopathology that has been studied, we view parental emotional behavioral well-being and positive parenting as critical components of prevention and health promotion in children and adolescents. As such, next we will briefly review the research surrounding parental psychopathology and positive parenting. Then keeping in mind that emotional behavioral health is a key component of overall health, we present the emerging science supporting the health-promoting capacities of: music, mindfulness, nutrition, and exercise.

Established Modalities for Child and Adolescent Psychiatry

Parental Psychopathology

The presence of a parent with psychopathology serves as a nonspecific risk factor for multiple forms of offspring psychopathology including internalizing, externalizing, and substance use disorders (61–63). The risk associated with parental psychopathology is conferred via genetic and environmental mechanisms (10,64–66). Yet even when the influence of prominent environmental risk factors (e.g., childhood adversity, low socioeconomic status) are controlled for, a child who has a parent with psychopathology is still 1.5 to 8 times more likely to develop emotional

behavioral illness (67,68).

Research also suggests, however, that when parental psychopathology is treated, the risk conferred to offspring is reduced. For example, children who have a parent with a depressive disorder are four times more likely to develop psychopathology (61). Yet, when maternal depression is treated, children show reduced rates of psychopathology, improved academic performance, and enhanced overall functioning (69,70). The reductions in child problem behaviors associated with the successful treatment of maternal depression are sustained at 6-month and 1- and 4-year follow-ups (69,71–73). Thus, to date research suggests that, treating parental psychopathology, can promote offspring mental health.

Parent Training

Along with parental psychopathology, the parenting practices employed within a home exert an influence on the environment in which a child's development occurs. It has been suggested that a potential mechanism through which some forms of parental psychopathology confer risk for child psychopathology is via parenting behavior. Indeed, research suggests that parental psychopathology can compromise effective parenting behavior (74), and that a reciprocal relationship exists between parenting behavior and child psychopathology (75).

Parent training programs are designed to provide parents with parenting strategies to increase their child's compliance and prosocial behavior, and reduce their child's oppositional and aggressive behavior. Some of the most well-researched behavioral parent training programs are: Helping the Noncompliant Child (76), Incredible Years (77), Parent Management Training (78), and Triple-P (79).

It is well established that parent training programs are effective treatments for children struggling with clinically significant disruptive and externalizing behavior (80). However, as PMT's designation as a model preventive intervention suggests, parent training is also effective in children and adolescents without clinically significant levels of psychopathology. Even among otherwise healthy toddlers, the preventative use of parent training has been associated with reductions in the development of externalizing and disruptive behavior over a 5-year period (81). Therefore, research suggests that effective and positive parenting can both treat and prevent the development of child psychopathology.

Emerging Modalities for Child and Adolescent Psychiatry

Beyond the established role of parental psychopathology and parent training in developmental psychopathology, there are a number of health-promoting modalities that have an emerging evidence base and are established enough, with little risk, that we believe they can begin to be implemented in standard practice. These are

mindfulness training, nutrition, exercise, and music training.

Mindfulness

As it applies to modern western health care, mindfulness has been defined as the ability to disengage from one's beliefs, thoughts, and actions, and attend to moment-to-moment experience in a nonjudgmental manner (82). It has been suggested that such a state can be fostered using a variety of techniques (e.g., mindfulness meditation, mindful breathing, mindful movement, and short meditations during the course of the day) (83).

Over the last 35 years, mindfulness has been incorporated into a number of psychosocial interventions including: Dialectical Behavior Therapy (DBT) (84), Acceptance and Commitment Therapy (ACT) (85), Mindfulness-Based Stress Reduction (MBSR) (86), and Mindfulness-Based Cognitive Therapy (MBCT) (87) with research suggesting that such interventions can effectively treat a range of conditions, including: Borderline Personality Disorder (88), anxiety disorders (89), mood disorders (90), eating disorders (91), high stress levels (92), and chronic pain (83,93).

Beyond mindfulness' application to clinical populations, research also suggests that mindfulness may be a helpful strategy for individuals who do not evidence clinically significant levels of psychopathology. Among otherwise healthy adults, MBSR is associated with increases in mindfulness that temporally precede reductions in negative affect (94). Similarly, among college students without clinical levels of psychopathology, MBSR is associated with decreases in the symptoms of psychopathology (83,95).

A body of work suggests that mindfulness may be particularly beneficial for women during pregnancy. Both randomized controlled (96,97) and uncontrolled (98) studies suggest that mindfulness training for pregnant women is associated with reductions in physical pain, stress, depression, and anxiety. Maternal stress and anxiety during pregnancy have been associated with infants being born preterm and at low birth weights (99), as well as a cognitive, emotional, and developmental outcomes in infancy and childhood (97,100). Thus, some have argued that helping mothers achieve emotional behavioral wellness during pregnancy may be a means to prevent the development of negative outcomes in children (97,101).

In addition to work suggesting that mindfulness may be an effective intervention for adults, research also suggests that mindfulness may be an effective prevention and treatment strategy in children. Meta-analytic work suggests that mindfulness interventions have a small-to-moderate effect on emotional behavioral symptoms in general populations of children and adolescents, and a slightly larger effect on emotional behavioral symptoms in clinical populations (102,103). However, while mindfulness interventions may effectively promote resilience in universal populations of children and treat psychopathology in children with mental illness,

more randomized controlled trials exploring the affect of mindfulness training in children are needed (104).

Nutrition

It has long been established that consuming a nutritious and well-balanced diet is a critical component of overall wellness. Research suggests that a healthy diet contributes to enhanced cardiovascular health (105), reduced rates of cancer, and longevity (106). Recently, research has begun to suggest that there is an association between nutrition and mental health.

In both children and adults, diet quality has been demonstrated to influence learning, memory, and mood (107,108). In adolescents, internalizing and externalizing disorders are positively associated with increased consumption of fast food, red meat, and sugar, and negatively associated with increased consumption of fresh fruits and vegetables (109). Prospective longitudinal work suggests that among adolescents diet quality may be causally related to mental health (110). In adults, diets of low quality are associated with increased rates of anxiety and depression, reductions in molecular substrates involved in cognitive processing, and increased risk for neurologic disorders (108).

In addition to overall diet quality, a variety of nutritional deficiencies have been associated with emotional behavioral illness. Cross-sectional work with adults suggests that low serum cholesterol is associated with antisocial, violent, and self-injurious behavior (111). Cross-sectional work with children suggests that iron and zinc deficiencies are associated with externalizing behavior and Attention-Deficit Hyperactivity Disorder (ADHD), respectively (111). Longitudinal work with children suggests that zinc, iron, and vitamin B deficiencies during early childhood are associated with externalizing disorders during adolescence (111). In children, diets low in omega-3 fatty acids have been associated with hyperactivity, learning disorders, and behavioral problems, and recent interventional work suggests that omega-3 fatty acid supplementation results in reductions in externalizing behaviors (111). It has been hypothesized that this association between nutritional deficiencies and mental health may be mediated by epigenetic changes and altered brain structure and function (111).

Exercise

Engaging in physical exercise is associated with a decreased risk for a host of general medical conditions including obesity, diabetes, and cardiovascular disease (112). It has also been suggested that physical exercise may be a viable preventive intervention and treatment for psychopathology (113).

The majority of research exploring the effects of exercise on clinically significant psychopathology in adults has explored the influence of exercise on depression and

anxiety (114). Among adults with depression, meta-analytic work suggests that exercise has a moderate-to-strong effect on the symptoms of depression (115). Among adults with anxiety, results are inconsistent with some research suggesting that exercise has a minimal effect on the symptoms of anxiety (116) and others reporting a large effect (117).

Among otherwise healthy adults, correlational work suggests that individuals who are regularly physically active report fewer symptoms of anxiety and depression and have 45% lower odds of developing a depressive disorder and between 24% and 48% lower odds of developing an anxiety disorder (118). While such work does not elucidate the direction of these effects, a recent meta-meta-analysis using data from 400 randomized trials and 14,000 participants suggests that among adults with nonclinical levels of anxiety and depression, exercise results in a medium but significant reductive effect on depressive symptoms, and a small but significant reductive effect on the symptoms of anxiety (114). Such work suggests that exercise may be a viable preventive intervention among individuals with subclinical symptomatology.

Research has also explored the relationship between physical activity and psychopathology in children and adolescents. Research suggests that physical activity appears to have a small but beneficial effect on the symptoms of anxiety and depression, a large effect on self-esteem, and to be associated with improved cognitive performance, classroom behavior, and academic achievement (119). In addition, meta-analytic work suggests that in children aerobic exercise programs have a moderate-to-large effect on the symptoms of ADHD (120).

Music

Recently, there has been an explosion of interest in the neurophysiologic, cognitive, and behavioral correlates of playing music. To date, research suggests that playing a musical instrument is associated with alterations in brain structure and function, enhanced cognitive functioning, and improvements in academic performance.

A long-standing body of work with children and adults suggests that relative to amateur musicians and nonmusicians, practiced musicians evidence structural and functional differences in various regions of the brain. In adults, practiced musicians evidence structural differences in the: primary sensorimotor cortex, superior premotor cortex, superior parietal cortex, primary auditory cortex, cerebellum, inferior frontal gyrus, and lateral temporal lobe (121). Research among adult professional musicians, suggests positive associations between music training during childhood, adolescence, and adulthood and white matter tract development (122). Similarly, cross-sectional work with children suggests that relative to children who do not play musical instruments, children who play an instrument evidence increased gray matter in the sensorimotor cortex and occipital lobe, increased activation of the temporal lobe during rhythmic and melodic discrimination tasks (123), and distinct

patterns of cortical thickness maturation in the dorsolateral prefrontal cortex (124).

Given the cross-sectional and correlational nature of much of the research on music, such work cannot address whether structural and functional brain differences are a consequence of increased musical practice, or rather reflect underlying neuroanatomical differences that predate exposure to music. Recently, however, research with children has begun to suggest that musical training may indeed be causally related to both changes in cognition, as well as changes in brain structure and function. Relative to a control group of children matched on age, verbal IQ, and socioeconomic status (SES), children who played an instrument for 1 year evidenced significantly greater fine motor and visual discrimination skills (123). Relative to a control group, children who engage in 15 months of musical training evidence improvements in motor and auditory skills, as well as structural changes in the right precentral gyrus, the corpus callosum, the right primary auditory region, the pericingulate, and the left middle occipital lobe (125).

In children, music training may be causally related to changes in cognition. Relative to a control group who did not receive musical instruction, 5-year-old children who received 20 minutes of twice weekly music instruction showed improvements in spatial temporal tasks after 4 months as well as after 8 months (126). Research with low-income 4 to 5 year olds also suggests that relative to a control group, children receiving a 30-week, 75-minute daily music instruction evidence improvements in visuospatial reasoning (127).

Despite such evidence, the majority of children in America do not regularly play a musical instrument. Indeed, roughly 74% of 10th graders and 86% of 12th graders “rarely or never” participate in out-of-school music lessons (124). There are, however, two emerging preventive intervention programs that use music training as a means to offset risk: El Sistema (128) and the Harmony Project (HP) (129).

El Sistema originated in Caracas, Venezuela, and is a music education program serving more than 500,000 Venezuelan children. More recently, El Sistema has been implemented in the United States, and currently more than 2 million at-risk American children partake in the El Sistema curriculum. The El Sistema program has resulted in: a 20% reduction in school dropout, a 22% increase in participation in community activities, and a 28% increase in employment among children who participate (128).

Similarly, the HP is a nonprofit organization based in the United States that provides music instruction and ensemble performance experiences for low-income youth. The HP is currently being implemented in 17 sites in Los Angeles as well as 7 other major cities across the United States. Students participating in the HP receive several hours of musical instruction per week (129). Children enrolled in the HP demonstrate significant gains in neural and auditory processing mechanisms linked with reading and language skills (130,131). In addition, participating in the HP is associated with parent-rated improvements in mood, health, grades, and behaviors. Relative to schools that do not participate in the HP, schools participating in the HP

evidence improvements in high school graduation rates and college attendance (129). While music training is an integral part of the HP, the HP also utilizes a mentorship model and thereby offsets risk by capitalizing on other known protective factors (e.g., social support).

The Vermont Family-Based Approach

Examining these emerging domains of prevention and health promotion, it becomes evident that few, if any, of the evidence-based preventive interventions described above take into account the emerging literature from neuroscience, psychology, and genetics to incorporate treating family psychopathology, positive parenting, mindfulness, nutrition, music training, and exercise into one cohesive approach. With that in mind, we present here an emerging clinical and public health paradigm, The Vermont Family-Based Approach (VFBA).

The VFBA was developed by James J. Hudziak, M.D. at the Vermont Center for Children, Youth, and Families and is designed to integrate research on developmental psychopathology into a family-based therapeutic intervention. The VFBA is conceptualized as a means to both treat and prevent the development of emotional behavioral illness in children, and is based on a few central tenets: (1) emotional behavioral health is the cornerstone of all health; (2) all health is familial; (3) health promotion, prevention, and intervention should take into account the emerging science of music, mindfulness, nutrition, and exercise.

VFBA Tenet #1: *Emotional behavioral health is the foundation of all health.*

This concept arises from the emerging literature on the role of psychopathology in nearly every other medical discipline. There is nowhere that this is more evident than in the role of adverse childhood experiences on a wide range of child and adult pathologies from obesity and diabetes to sexually transmitted diseases (6). This literature demonstrates that the way that experiences are managed during childhood does not just affect later mood and behavior, but also affects other medical conditions seemingly “unrelated” to psychopathology. Further, attending to patients’ emotional behavioral health allows for more adequate treatment of multiple other conditions including heart disease (132), cancer (133), and diabetes (134), again demonstrating that the cornerstone of health promotion, prevention, and intervention of medical conditions is attending to emotional behavioral health.

VFBA Tenet #2: *All health is familial.*

In the VFBA paradigm, the treatment of parental psychopathology and the utilization of parent training are viewed as means to both treat and prevent the development of child psychopathology. Given that parental psychopathology is a known risk factor for child psychopathology, the VFBA seeks to improve child and

adolescent mental health by providing mental health care to both the child and his or her parents. The VFBA is based on the premise that addressing parents' clinical and subclinical mental health needs will help to prevent and facilitate the treatment of existent emotional behavioral illness in children.

Along with parental psychopathology, the parenting practices employed within a home exert an influence on the environment in which a child's development occurs. As such, in addition to addressing both children's and parents' mental health needs, the VFBA utilizes evidence-based parent training strategies to improve parent–child dynamics. Thus, within the VFBA paradigm parenting training is conceptualized as a treatment to help families who are struggling with child psychopathology, as well as a means to bolster parenting skills and prevent the development of psychopathology among children who are otherwise healthy.

VFBA Tenet #3: *Health promotion, prevention, and intervention should take into account emerging science of mindfulness, nutrition, exercise, and music.*

The VFBA promotes family wellness by encouraging the entire family to engage in health-promoting activities including: mindfulness training, healthy eating, exercise, and music training. In this way, the components of the VFBA serve as both effective treatments for children and parents with psychopathology, as well as selective, indicated, and universal preventive interventions for families who are well.

Mindfulness

Given the growing body of empirical evidence suggesting mindfulness' utility as both a treatment and a preventive intervention strategy, there is reason to be optimistic about mindfulness' role in mental health. However, while there are some randomized controlled studies on the effects of mindfulness-based interventions (e.g., MBCT) many studies on the effects of mindfulness are compromised by small sample sizes, lack of control groups, lack of randomization, and lack of data on treatment compliance (75). In particular, more well-controlled work is needed on the effect of mindfulness in children. Nonetheless, the state of the evidence is such that within the VFBA paradigm mindfulness is conceptualized as a health-promoting activity. As such, parents and children who are well, at risk, and struggling with psychopathology are encouraged to engage in mindfulness practices.

Nutrition

Given the body of research implicating overall diet quality and specific nutritional deficiencies in general medical as well as emotional behavioral disorders, the VFBA paradigm conceptualizes a healthy well-balanced diet as a treatment strategy among families who are struggling with emotional behavioral illness, as well as a

preventive intervention among those who are well.

Exercise

While it cannot be concluded with certainty that the relationship between exercise and mental health is direct and causal, it seems reasonable to hypothesize that the reductive effects of physical activity on psychopathology “cannot be explained by a single mechanism acting in isolation; rather the effects are most likely due to the contribution of several mechanisms (e.g., mood, feelings of mastery, self-efficacy) and neurophysiologic (hippocampal neurogenesis, hypothalamic–pituitary–adrenal axis regulation)” (107). Given the available research, the VFBA paradigm conceptualizes exercise as a viable treatment and preventive strategy, and encourages parents and children to engage in physical activity through structured exercise programs, often using fitness coaching and positive reinforcement.

Music

Because of the large body of research suggesting that music training is associated with changes in brain structure and function, and the findings from school-based programs such as El Sistema and HP that music training is associated with improvement in cognition as well as improved academic performance, the VFBA strongly encourages a musical component for the entire family. Although a randomized controlled trial using clinical samples has yet to establish a direct relationship between music training and reductions in psychopathology, the available evidence suggesting music training’s utility as a preventive strategy as well as music training’s impact on neuroanatomy has led to its incorporation into the VFBA. Within the VFBA paradigm, children who are well and children who are struggling with emotional behavioral illness, along with their families, are encouraged to play a musical instrument.

Demonstrating the Effectiveness of the VFBA

While the effectiveness of each of the essential components of the VFBA has been demonstrated, the VFBA in its entirety has not been formally tested. A randomized clinical trial of the VFBA paradigm is currently underway at the University of Vermont Medical Center. This trial is projected to include 120 to 160 families with a child between the ages of 3 and 6. Families enrolled in the treatment condition will be partnered with a family wellness coach who will help them implement a health and wellness plan based on the results of a family-wide assessment. This assessment will include standardized measures of each family members’ emotional behavioral health, as well as assessment of the health-promoting activities in which they engage. Each family’s health and wellness plan will be tailored to their specific needs, but

will rely on the fundamental principles of the VFBA: family-wide mental health care, positive parenting strategies, mindfulness, nutrition, exercise, and music training.

Summary

Child and adolescent psychiatry is now perfectly positioned to play a critical role in health promotion, illness prevention, and family-based intervention. We are the only medical professionals who understand the impact of the environment on: the genome (epigenome), the structure and function of the developing brain, and related thoughts, feelings, and behaviors (symptoms). We can prescribe wellness to all children (e.g., mindfulness, exercise, nutrition, sleep, music, etc.), regardless of whether or not they are at risk or already struggling with emotional behavioral problems. We can assist in prevention by assuring that all parents have access to parent training, and promote the idea that treating parental emotional behavioral problems is a far more powerful tool than ignoring such problems. We can become the field that recognizes the importance of prescribing social supports and education around the difficult task of raising healthy children. And, when we treat children who are in the grips of psychopathology, we should do so in a family-based manner that includes concomitant health promotion and illness prevention perscriptions. Basic developmental neuroscience and genomic evidence exist, the ACEs study provides a perfect platform for national attention, and accountable care is an invitation to fund reform that will place child and adolescent psychiatry at the center of health care reform.

3.3 NEUROBIOLOGY AND GENETICS

CHAPTER 3.3.1 ■ FROM GENES TO BRAIN: DEVELOPMENTAL NEUROBIOLOGY

HANNA E. STEVENS, JAMES F. LECKMAN, PAUL J. LOMBROSO, AND FLORA M. VACCARINO

Human beings are complex living organisms that can be generally characterized as a species by their appearance and behavior at each point in their life cycle. Many of these characteristics are uniquely human, such as language that facilitates interpersonal communication and permits a meaningful interplay of ideas and emotions. Other characteristics, such as affection and aggression, are less distinctive and place our species as one among many that populate the earth. Scientific advances over the past 150 years clearly indicate that hereditary factors, transmitted from generation to generation, account for much of the variation among and within species. Genetic factors are essential for the general characteristics all humans share and their unfolding during development, which is orchestrated at many levels—from the higher order interplay of the environment and the individual to the microscopic interactions inside cell nuclei. Although the complexities of human existence cannot be reduced simply to the effects of genes, it is inescapable that genetic factors and their regulation over the course of development provide the biologic basis for many of our potentialities and vulnerabilities as human beings (1).

Our genetic endowment as a species is a unique collection of discrete units of heredity (genes and the regulatory regions of our genomes) that are linearly arranged on 46 chromosomes (22 pairs of homologous chromosomes and two sex chromosomes) (Figure 3.3.1.1). Analysis of the data compiled in the human genome project (2,3) has identified approximately 20,000 genes in our genome (4).

It is now clear that genes, canonically defined as those parts of DNA that code for proteins, represent only 1% of the nuclear DNA and are not the only elements that encode information in the nucleus. Until recently, the function of the vast majority of the three billion bases of the human genome outside of genes was not known and was labeled as “junk DNA.” The Encyclopedia of DNA Elements (ENCODE) project, through large scale integrative analyses of many different cells types, has undertaken a systematic mapping of all DNA elements and has assigned regulatory functions to 80% of what was previously considered “junk” (5).

Our genes and other DNA elements make us both alike and different from other organisms. Although the precise genetic determinants of our interspecies similarities and differences are largely obscure, it is probable that many of the responsible genetic factors will be identified. For example, sequence differences between human and chimpanzees at specific gene enhancers drive species-specific activity in cranial neural crest cells, leading to emergence of human craniofacial traits (6). Investigators are in the midst of discovering the cascade of genes that have contributed to the remarkable neuroanatomical and functional evolution of the cerebral neocortices

across different mammalian species over the past 50 million years (7–10). Intriguingly, variation of gene expression from "junk DNA," rather than variation in protein sequence, is almost certainly the dominant factor in human brain evolution (10). Such changes are thought to have led to the creation of many new combinatorial expression patterns during development and ultimately to the formation of distinct neuronal circuits (11).

Genetic factors also contribute to variations within our species. A large number of physical and psychological traits, including gender, height, and intelligence, are at least partially under genetic control. One need only examine the striking physical and psychological similarities between monozygotic (genetically identical) twins reared apart to recognize the powerful influence of genes in determining who we are (12). Some of these differences, such as gender, are due to differences in the number and type of genes present in the individual. For example, genes on the Y chromosome are present in males. Other variations are due to differences in the linear sequence of nucleotides (polymorphic alleles) of specific genes and DNA regulatory elements that are distributed within the population. While most polymorphisms are "silent" and do not change protein activity, some changes lead to new amino acids in proteins, resulting in differences in the structure, activity, or amount of the protein and contribute to traits such as blood type, height, or eye color. In other cases, polymorphisms may render an individual more susceptible to additional factors, be they genetic or environmental that in turn lead to observable differences. These include sequence changes in gene regulatory regions effecting differential binding of transcription factors and sequence and quantity changes in regulatory RNAs.
FIGURE 3.3.1.1. Depiction of high-resolution banded human chromosomes. (Adapted from *Yale-HHMI Human Gene Mapping Library Chromosome Plots*, Number 5. New Haven, CT, Howard Hughes Medical Institute, 1989.)

The Human Genome Project was very important for its systematic study of allelic variation but also for its discovery of larger variations in DNA among individuals. Variation in the “dosage” or copy number of genes was discovered in all individuals studied (13). These copy number variations (CNVs) occur when a gene or portion of DNA is removed—termed deletions—or when a gene or portion of DNA is added—termed duplications. Deletions and duplication can involve just few nucleotides

(called InDels) or encompass thousand to millions of base pairs spanning multiple genes (large CNVs). CNVs actually occur surprisingly frequently, accounting for about 13% of each person's DNA (14). CNVs are mostly inherited and are thought to contribute to both unique traits of our human species—such as having enough copies of a gene for the enzyme amylase to digest the food we eat—and to individual variation. On average, a typical genome varies from the reference human genome at 4 to 5 million sites, of which 99.9% are single nucleotide variants (SNVs) or InDels and about 3,000 are large CNVs (15–18). Some allelic variation and CNVs are so significant that we use the term mutation or disease-associated CNV to signify that the changes will usually lead to disease states such as Rett syndrome, Huntington disease, Marfan syndrome, or sickle cell anemia, disorders in which ameliorating factors will have little effect.

Differences in the expression of genes over the life span are critically important for the physical and cognitive functioning of individual organisms, from *Drosophila* to humans. Not all genes are active at the same time. For example, the hemoglobin genes active during fetal life are different from those that are active in adulthood. These differences are also responsible for the allocation of specific characteristics and functions to specific cells of the body (e.g., for making muscle cells different from brain cells), and are orchestrated by master developmental genes. Differences in gene expression can be also induced by the environment and by experience. However, the influence of these external factors is stronger at specific phases of development such as sensitive periods for learning and social affiliation during juvenile periods.

The next sections, Genes, and Regulation of Gene Function, present a condensed summary of some of the fundamental aspects of the structure and function of genes and gene products. Several excellent general references cover this material in greater depth (19,20).

GENES

Mendel first postulated the existence of discrete hereditary factors or genes in 1865 (21) but their importance was not appreciated until the early 1900s. Genes are arranged linearly on chromosomes that are found in the nuclei of most cells (Figure 3.3.1.2). They are composed of DNA, double helix strings of nucleotides (molecules that contain a sugar moiety, a phosphate group, and a base) that are linked together. Four nucleotides are found in DNA. Two contain purine bases (adenine and guanine) and two contain pyrimidine bases (thymine and cytosine). Hydrogen bonds between complementary base pairs (adenine binds to thymine and guanine to cytosine) (Figure 3.3.1.3) provide the basis for replication of the information, which is essential for all the cells of our body to arise from a single embryonic cell. Since each strand in the double helix is exactly complementary to the other, knowing the sequence of one

strand provides precise knowledge of the sequence of the other.
FIGURE 3.3.1.2. The structure of chromosomes. Chromosomes are thread-like packages of DNA in the nucleus of a cell. This drawing also depicts a diagram of the DNA double helix in its common form showing the orientation of the two complementary strands and the wrapping of DNA around histone cores. (Adapted from the *Glossary of Genetic Terms* and associated illustrations found on the website of the National Genome Research Institute, 2000.)
FIGURE 3.3.1.3. Chemical structure of DNA, showing the phosphodiester 3′5′ linkages that connect the nucleotides. (Adapted from Watson JD, Hopkins NH, Roberts JW, et al.: *Molecular Biology of the Cell*. Menlo Park, CA, Benjamin/Cummings, 1987.)

The sequence of nucleotides determines the specification and order of the amino acids in the protein encoded by the gene. As a consequence, the information contained in DNA provides the instructions for all cellular functions, including growth and cell division, regulation of gene expression, and maintenance of a diversified population of cells that are necessary for the success of a complex organism.

In order for temporary or time-sensitive expression of genes to occur, a more

temporary RNA copy of the information is created. A gene is first transcribed, or complementarily copied, from one DNA strand into what is called a pre-RNA transcript. This is then processed to produce the mature messenger RNA (mRNA), typically by bringing together the sequences that actually encode for the eventual protein (exons) and removing the intervening sequences (introns) that do not contain coding sequences. Mature mRNA molecules are rapidly transported out of the nucleus, where they serve as the template for protein synthesis.

The translation of a message into a specific amino acid sequence occurs at ribosomes located either in the cytoplasm or attached to the endoplasmic reticulum. The amino acid sequence is determined by the sequence of bases, with sets of three bases constituting a codon that stands for one amino acid. At the ribosome, codons of an mRNA molecule bind to complementary anticodons of transfer RNAs (tRNAs), which then transfer specific amino acids to a growing protein chain, first proposed by Crick et al. (22).

While genes are extremely stable and precisely copied when cells divide, any mistakes that occur could disturb the normal sequence of amino acids in the encoded proteins. There are a number of proteins within the nucleus whose function is to prevent, recognize, and repair errors within the DNA sequence. Very rarely, however, mistakes go uncorrected and will result in "*de novo*" changes in the original nucleotide sequence. Any error in DNA sequence or copy number that is not repaired will result in a somatic mutation in a particular cell, mutation that will be transmitted through that cell's lineage and, if that cell is a progenitor, amplified in many generations of cell division. The majority of such changes do not affect the proteins made as they occur in regions on the DNA molecule that are not involved in encoding proteins. However, changes that occur within the sequence that encodes for protein or within regulatory portions of genes may have functional consequences. First, they may change the enzymatic function or regulation of the protein. Second, if a critical amino acid or gene regulatory region is mutated, there may be dramatic changes in the cell and, ultimately, in the organism. This capacity for change can, if occurring in germline cells and if leading to positive consequences, serve as the basis for evolution.

REGULATION OF GENE FUNCTION

According to some estimates, about 1% of the genome is expressed at a given time in higher eukaryotic cells (20). Regulation of gene function—across development, for tissue specificity or in response to the environment—can occur at any of the many steps required for gene expression (Figure 3.3.1.4). By correlating RNA abundance and processing of a specific gene with the chromatin structure and variation in nucleotide sequence of DNA, it has been demonstrated that most of the variation in gene expression can be explained by sequence or structural changes within non–

protein-coding regions of DNA, which in turn change transcription factor binding at enhancers and promoters for that gene. These processes are described in the next two subsections, "transcription factors" and "epigenetic regulation."

The vast regions of DNA that are not genes themselves are one of the newest areas of discovery in genetics. This "Junk" DNA is far from useless, containing multiple different kinds of nucleotide sequences that play fundamental roles in gene regulation, cell function, and development. Furthermore, many mutations associated with psychiatric disorders through genome-wide association studies (GWAS) reside within these regions. The largest component of non–gene-encoding DNA, 62% of the genome, are sequences that are transcribed into RNA molecules of all sizes that are not translated into proteins (23). There are over 70,000 novel elements of this kind, not previously annotated, which outnumber the already known 20,000 or so protein-coding genes (24).

Some types of non–protein-coding RNA have roles that are well understood, including RNA molecules used in translation (transfer RNA and ribosomal RNA, both of which are part of the protein-making machinery). Others have regulatory functions for genes, either in the nucleus through RNA–DNA binding or in the cytoplasm, through RNA–RNA binding. Interestingly, the majority of novel RNAs, particularly those over 200 nucleotides, are cell-type specific. Conversely, less than 10% of the protein-coding genes are cell-type specific (24). Therefore, noncoding RNAs contribute more to cell-line specificity than protein-coding genes and are likely to be more involved in cell fate and cell lineage determination during development.

Still other regions of DNA regulate gene expression. Indeed, a large novel component of the genome uncovered by the ENCODE project is represented by regulatory elements, DNA regions that bind proteins to regulate the extent that a gene is transcribed. Only a small minority of such sites is active in each cell type. Almost all of these regulatory elements are located between introns or between genes (25).

As novel noncoding RNAs and regulatory elements are largely cell-type specific, it is of high interest to discover those involved in brain tissue. In this regard, the PsychENCODE project will begin exploring this landscape of transcription in the human brain, both in normal development and in neuropsychiatric disorders (10,26).

Transcription Factors

Transcription of a gene into mRNA is initiated by the binding of RNA polymerase II and a complex of regulatory proteins termed transcription factors to the regulatory region of a gene, termed the promoter. Regulatory regions are usually found immediately upstream of the transcriptional start site. Other highly conserved DNA sequences have been identified that either "enhance" or "repress" the transcription of target genes. These sequences, called "enhancers," are usually found near the

regulatory promoter region or in further upstream regions of DNA. These allow the RNA polymerase II complex to bind more, or less, efficiently and thus modulate transcription of the gene. In this way, specific sets of genes are expressed while others are repressed, depending on the precise mixture of enhancers, repressors, and transcription factors present in the cell. It is now emerging that mammalian corticogenesis involves a high level of coordination in the expression of transcription factors and other regulatory elements across multiple developmental pathways (10). Mutations in nucleotide sequence that occur within the promoter and/or enhancer regions of genes could have a dramatic effect on the expression of the encoded protein by disrupting the binding sites of the transcriptional machinery. Indeed, SNVs that influence gene expression and splicing patterns have been shown to fall within regulatory elements in the genome (27).

There are several classes of DNA-binding proteins that regulate transcription. The best characterized contain conserved amino acid regions that bind to specific enhancer or promoter sequences. For example, *homeodomain* transcription factors have a highly conserved 60-amino acid region that binds to specific DNA sequences in the regulatory regions of multiple genes that encode for proteins required during development (28). Others known as *zinc fingers* and *leucine zippers* also bind to DNA regulatory sequences within promoters and enhancers and regulate transcription (29,30). It is interesting to note that the discovery of the structure of these endogenous molecules and other molecules in bacteria has itself led to further discovery of research tools (Zinc finger, TALEN, and CRISPR/cas nucleases) that have been used to change or disrupt gene sequences in zebrafish, rodents, and cultured human cells in order to study their function (31,32).

Epigenetic Regulation

Another major mechanism by which genes are regulated is through “epigenetic” mechanisms—literally changing structures “around” the DNA sequence. This generally means changes in the three-dimensional structure and organization of DNA, which determines the portions that are “open” to bind regulatory RNA and transcription factors, and the portions that are excluded from transcription. The epigenetic “silencing” of genes can occur through enzymes adding or removing methyl or acetyl groups from the histones around which DNA is coiled. Another silencing mechanism occurs through addition of methyl groups to DNA itself. Repression of gene expression in this manner is remarkably efficient. For example, changes in expression of globin or growth factor genes due to epigenetic regulation can result in ratios of 1:10,000,000 or more of RNAs in cells repressing these genes compared with those where these genes are actively transcribed (33,34).
FIGURE 3.3.1.4. Sequence of events leading to gene expression. A protein-coding gene comprises a stretch of genomic DNA that contains instructions for making the protein, as well as adjacent control regions—promoters and enhancers—where the gene's trans criptional mechanism is switched on or off. The promoter region is the site at which RNA polymerase II binds and initiates transcription. Enhancer regions may be thousands of base pairs distant from the promoter. Transcription of the gene into mRNA

may be either stimulated or inhibited by transcription factors that bind to promoter and enhancer regions. The mRNA formed by transcription is spliced to remove introns and processed within the cell nucleus to produce mRNAs that are exported to the cytoplasm for translation into protein. Some proteins go through posttranslational modification to become biologically active. The four examples depicted include: cleavage of precursor proteins, conformational change through covalent cysteine–cysteine (C–C) bonds, phosphorylation of serine (S), threonine (T), or tyrosine (Y) (*black squares*), and glycosylation of asparagine (N, *branching motif*).

Histone methylation and acetylation have a direct impact on the compactness of the DNA/histone complexes. In normal transcription, histone acetylation removes the electrical charge that attracts DNA to the histone and causes an unwinding of the DNA that permits the transcriptional machinery to access the DNA. Consequently, factors that activate histone acetylases promote gene transcription and those that activate histone deacetylases repress gene transcription. Histone methylation is a more complex mechanism that may either promote or repress gene transcription depending on exactly where the histones are methylated. Both processes are critical for the regulation of genes that play specific roles at different time points in development.

Within the promoters of most genes, DNA methylation can occur in “CpG islands” (DNA sequences rich in C + G nucleotides). Cytosine is the only nucleotide that can be replaced with a methylated version. Typically methylation of DNA in a CpG island will prevent activation of a promoter and therefore prevent transcription of a gene. Methyl-CpG–binding protein (Mecp2) binds to methylated CpG dinucleotides in the mammalian genome and recruits repressors (35,36). In addition, Mecp2 associates with DNA methyltransferases (37), which inhibit transcription via methylation of DNA. Repression of transcription via Mecp2 and associated proteins has emerged as an important factor in two neurodevelopmental disorders, Rett and fragile X syndrome (38) (see Chapter 3.3.3 for a more detailed examination of these syndromes).

Epigenetic regulation may also involve the methylation of cytosines within a gene itself. The exact role of this epigenetic modification is currently unknown but one possible role for methylation of gene exons may be to determine what exons are included and the eventual splicing of the gene transcript (39).

DNA in somatic tissue is characterized by a bimodal pattern of methylation, which is established through a series of developmental events (40). Very early in development, most DNA is unmethylated, but after implantation, a wave of *de novo* methylation modifies most of the genome, excluding the majority of CpG islands.

These genomic methylation patterns are broadly maintained during the life of the organism with each replication of chromosomes during cell division. As developmental events occur, specific needs for gene silencing or activation will result in changes to the methylation of promoter regions. These developmental processes also interact with methylation change from experience and even those inherited from either parent (discussed in later section: The Role of Early Life Experience) (41,42).

Methylation can also contribute to another type of "gene dosage" control, which is a crucial process in the regulation of genes. One example is the early coordinated inactivation of one of the two X chromosomes in women. Genes may be unexpressed due to genomic *imprinting,* which means repression. Imprinting is a process that occurs normally for some classes of gene loci by which the methylation of either the maternal or the paternal locus results in only one of the two inherited copies being expressed (43,44). This process on occasion has been associated with disease when the silencing of one of an individual's alleles unmasks problems that might otherwise be compensated in the other allele. One example of this concerns two distinctively different developmental disorders, Prader–Willi and Angelman syndrome, caused by differential imprinting of the same region of the maternal or paternal chromosome 15 (see Chapter 3.3.3 for a further discussion of imprinting).

Posttranscriptional Regulation

Transcribed mRNA typically goes through a number of modifications before it leaves the nucleus. As described above, pre-RNA molecules are spliced to form a mature message containing the sequence of nucleotides that encode the amino acids that form the protein. Multiple different splice sites can be present within a pre-RNA transcript and allow for the exons of the gene to be brought together in different combinations, sometimes excluding one or more exons. This results in alternative splicing into several different mRNAs. In this way, a single gene may produce similar proteins that differ in certain critical amino acid regions, or domains. These proteins may have different enzymatic functions or binding affinities for target proteins. Alternatively spliced messages are enriched within the central nervous system (CNS), where the different exon combinations may be expressed at different developmental periods (45). For example, one version of a protein may only be expressed during embryonic development or may be targeted to the nucleus to regulate gene transcription. An alternatively spliced adult form may have a novel domain that targets it to the synapse, where it participates in specific signaling pathways.

Another gene regulatory mechanism involves the addition of long stretches of adenine nucleotides, the poly(A) tail, to the mRNA message prior to its being shuttled out of the nucleus. The stability of a mature mRNA is a critical determinant

of how many copies of a protein will be synthesized by the ribosomal apparatus. Certain base sequences in the message as well as the poly(A) tail are thought to influence the stability of many mRNA molecules and their rate of degradation. Translation of mRNA to protein can also be modified through the regulation of RNA-binding proteins necessary for translation. Mutations in proteins that underlie translation can lead to a number of developmental disorders including fragile X syndrome (46).

Noncoding RNAs

Interestingly, Frances Crick et al. hypothesized 70 years ago that RNA molecules themselves would be natural regulators of other RNAs due to their biochemical structure. However, the role of noncoding RNA molecules as regulators of mRNAs was not confirmed until the early 2000s (47).

There are two main classes of noncoding RNA, the long noncoding RNA (lncRNA) described above, which are larger than 200 nucleotides and mostly act in the nucleus, and the microRNAs. The latter are complementary in sequence to mRNAs, bind to mRNAs, and prevent them from being translated into proteins. The importance of these molecules in brain development is demonstrated by one prominent example: mutations of the Dicer gene, which codes for an enzyme involved in microRNA processing. Without functional Dicer gene products, microRNAs in general cannot be produced and multiple aspects of brain development are abnormal (48).

Posttranslational Modifications

Once a protein has been formed, it often undergoes further modification that will control how it contributes to overall cell function. One important posttranslational modification is termed phosphorylation, and refers to the addition of a phosphate group to the amino acids serine, threonine, or tyrosine on target proteins. The addition of this bulky negatively charged group often leads to a conformational change in the shape of a protein, with a previously hidden domain now exposed and the activity or intracellular localization of the protein changed (e.g., translocation from the cytoplasm to the nucleus).

Another posttranslational modification is the addition of a ubiquitin peptide to specific lysine residues on a target protein. Addition of a single ubiquitin molecule (monoubiquitination) may regulate the subcellular localization of a protein or its state of activity. The addition of a string of ubiquitin molecules to a lysine residue (polyubiquitination) targets the protein for degradation by the proteasome; this can rapidly decrease the levels of a protein. For example, many proteins in the synaptic compartment need to be degraded for the development of synaptic strengthening

between neurons.

There are additional posttranslational modifications that can occur. The crosslinking of sulfhydryl groups in two cysteine residues of a protein allows them to covalently bond together and stabilize the protein as it folds into a final tertiary structure. The tertiary structure of a protein often determines its activity level. Several other chemical modifications also occur, such as the glycosylation of the amino acid asparagine, the acetylation of the NH2 terminal amino acids, or the hydroxylation of proline and lysine residues. Glycosylation can change protein location, structure, and activity (20).

The removal of amino acids from a protein is another posttranslational modification. For example, neuropeptides like dynorphin are formed from the cleavage of precursor proteins at specific sites. Intriguingly, differential processing of prodynorphin, the initial dynorphin protein, in different tissues is commonplace, so that the form of dynorphin found in the anterior lobe of the pituitary is different from the form of dynorphin found in the neurointermediate lobe (49).

MICROENVIRONMENTAL INFLUENCES ON DEVELOPMENT

Growth factors are naturally occurring substances that regulate a variety of processes including cellular growth, proliferation, and differentiation (50,51). Growth factors typically act as signaling molecules between cells and have been implicated in a broad range of developmental processes in the CNS in which cell specification, growth, migration, and survival have to be coordinated across cell and tissue compartments.

For example, in early embryonic development, fibroblast growth factors (FGFs), WNT, bone morphogenetic proteins (BMPs), and sonic hedgehog (Shh), synthesized within the neural tube and/or diffusing from adjacent nonneural structures, determine the anteroposterior and dorsoventral identity of cells and subregions (52). The same factors are also critical for other aspects of brain growth. For example, basic fibroblast growth factor (FGF2) and other FGF family members, acting primarily through the FGF receptor 1 and FGFR2, are required for the growth of the hippocampus (53) and cerebral cortex (54) by regulating cell proliferation and neurogenesis (55–57). In postnatal development, different growth factor families, particularly neurotrophins which include brain-derived neurotrophic factor (BDNF), participate in the activity-dependent pruning of connections and synapses (58,59), processes underlying learning and memory (60). Thus, growth factors are required for both structural development and CNS functioning (61).

Growth factors are produced often in only minute amounts. Neurons compete for the small amounts of trophic factors present through receptors on their outer membranes. These receptors have an extracellular portion that binds to the growth factor and an intracellular domain that passes along the signal (Figure 3.3.1.5). The

intracellular domains are protein kinases that regulate themselves and other proteins through their phosphorylating actions. This generates a phosphorylation cascade, recruiting other proteins that are often themselves phosphorylated by the receptors, ultimately leading to the activation of transcription factors and the transcription of specific sets of genes. One of the best-studied signaling pathways is called “mitogen-activated protein kinase” (MAPK).
FIGURE 3.3.1.5. Signal transduction and the action of growth factors. Growth factors generate signals in a cell by binding to specific receptors on the plasma surface and initiating transcription, leading to the transcription and translation of proteins needed at that moment. Two molecules of a growth factor are shown binding to their receptor. The receptors are transmembrane tyrosine kinases receptors that associate with each other after ligand binding and phosphorylate each other at regulatory tyrosine residues. In their phosphorylated state, the receptors attract other signaling proteins, including the adapter protein SOS that activates the enzyme, Ras. The newly formed complex of proteins activates several kinase pathways, one of which is shown here (MAPKs). In this pathway, transcription factors (e.g., Elk-1, Jun) are activated by phosphorylation, often within the nucleus, and rapidly initiate the transcription of genes, some of which are themselves transcription factors (immediate early, or IE, genes). The IE transcription factors

initiate transcription of additional genes, and their mRNA messages are transported out of nucleus and translated into proteins, such as the ion channels shown. In this example, an ion channel is being synthesized and leads to an increased level of the second messenger, Ca^{2+}. (Adapted from Vaccarino FM, Lombroso PJ: Growth factors. *J Am Acad Child Adol Psychiatry* 37:789–790, 1998.)

The cascade of signals that growth factors initiate promote the growth, differentiation, and long-term survival of cells and the synaptic plasticity underlying learning during development. It is not surprising that mutations in some of these receptor proteins disrupt normal intracellular signaling, leading to a number of developmental disorders affecting the structure and function of the CNS (62,63).

Other molecules such as hormones (i.e., thyroid hormone) and immune factors (i.e., cytokines) are present in the systemic environment and may have more distant sources than brain intrinsically produced growth factors. However, little is known about how these factors play a role in the genetic regulation of brain development and research is ongoing to determine their importance in the developing brain.

GENES AND THE BUILDING OF THE BRAIN

The precise number of genes that regulate the growth and development of the CNS is unknown. Recently, Kang et al. (11) have estimated that at least ~15,000 genes are involved in this task. This figure does not include noncoding elements of DNA or constitutively expressed genes that maintain the basic functions of cellular life, including the regulation of the cell cycle, production of subcellular organelles, and maintenance of the cellular structure.

The process of development is a heritable feature of all organisms. The unfolding of gene expression must provide virtually all of the information necessary to guide the orderly succession of events that will transform portions of the fertilized egg into a fully developed CNS. The morphogenesis of the nervous system involves at least five major genetically regulated processes: the birth of specific cell types, their migration to their final destination, their growth, the development of neural connections, and cell death (64). A fundamental understanding of these processes requires precise knowledge of: (a) the developmental information relevant to the CNS that is encoded in the human genome, (b) how this information is regulated and utilized in "morphogenetic" time and space, and (c) how the products of these genes endow the differentiating and differentiated cells of the embryonic CNS with their functional characteristics. Although we remain largely ignorant of the critical determinants of these processes, remarkable progress toward understanding them has been made during the past three decades (65).

Genetic studies of the development of the CNS in flies, worms, and other model systems have recently been complemented by new methods for studying development in human cells, confirming that fundamental processes about genes and development also occur in humans. About 8 years ago, a method for studying development in human cells not derived from embryos was introduced, namely induced pluripotent stem cells (iPSCs). The breakthrough that began this line of research was the discovery that a handful of transcription factors could “reprogram” a cell from its mature, differentiated state to an immature pluripotent state (66). This method has been now used in an explosion of research on human cellular development but more critically for an understanding of disease, using skin cells or white blood cells reprogrammed from patients. The iPSC approach provides the ability to closely examine, manipulate, and perhaps even try to rescue the cellular development that goes awry in a person with a specific disease. In the case where known mutations have led to disease, such as Huntington disease, the iPSC approach may show the precise ways cells are affected and provide a model in which molecular treatments can be tested (67). In cases where a disease has an unknown etiology, such as autism spectrum disorders, the iPSC approach may help uncover specific causes (68). For example, the study of iPSCs from patients with autism spectrum disorders with macrocephaly has demonstrated that abnormal neuronal proliferation and differentiation likely occurs in patients and involves abnormally high levels of the transcription factor FOXG1 and altered activity of the genes it regulates (69). Research efforts with iPSCs represent a large part of the fertile ground upon which gene-based discoveries with promise for developmental disorders can be explored and brought to fruition.

Spatial Differentiation and Determination of Specific Cell Lineages

The creation of specific cell types requires the production of massive numbers of cells while maintaining a blueprint of the entire CNS, all guided by genes, their transcription, translation, and regulation through biosynthetic capacities of cells. Interestingly, cells of the early embryo are not mature enough to make the necessary molecular machinery and contain thousands of mRNAs formed during oogenesis and dormant within the egg until fertilization occurs. Interestingly, even early cell division depends on enough maternally derived cyclin protein to trigger mitosis (70). In some species, the set of maternal genes constitutes the majority of all genomic loci active during ontogeny (71).

Throughout the important phases of cell division in the CNS primordium, two important classes of highly conserved genes determine the fundamental tridimensional organization of the developing brain: segmentation and homeotic genes (72). These genes are clustered in the genome where their relative

chromosomal positions correspond to their relative expression throughout the body and the CNS (Figure 3.3.1.6). Acting as transcription factors, vertebrate versions of these genes such as *engrailed, wingless,* and *distalless* organize the transcription of other genes that establish distinctive cellular phenotypes of the different axes of the brain (i.e., rostral–caudal, dorsal–ventral) (73,74). This occurs in conjunction with morphogens such as FGFs and Shh. Other regulators of early developmental events in the cerebral cortex, including Notch and FGF signaling and the downstream Hes transcription factors, determine the switch of cell identity from a neuroepithelial to a radial glial stem cell (75). The evolution of the human brain to such a large size and with its large number of neurons likely depends on the generation of neurons from radial glial neural stem cells, a process regulated by transcription factors including Pax6 and the Neurogenins (76) as well as posttranslational regulation through ubiquitin ligase that degrade proteins determining stem cell identity (77). The intricate cascade of genetic and molecular events that lead to the development of the mammalian CNS is one of the most exciting stories in developmental neuroscience.

Not surprisingly, defects in the human homologues of homeodomain transcription factors and growth factor genes are being recognized with increasing frequency as a cause of cortical malformations due to aberrant neuronal proliferation and differentiation (78). Examples of this phenomenon are dystonia (79) and intellectual disability associated with schizencephaly or other disorders of cortical formation (80–82).

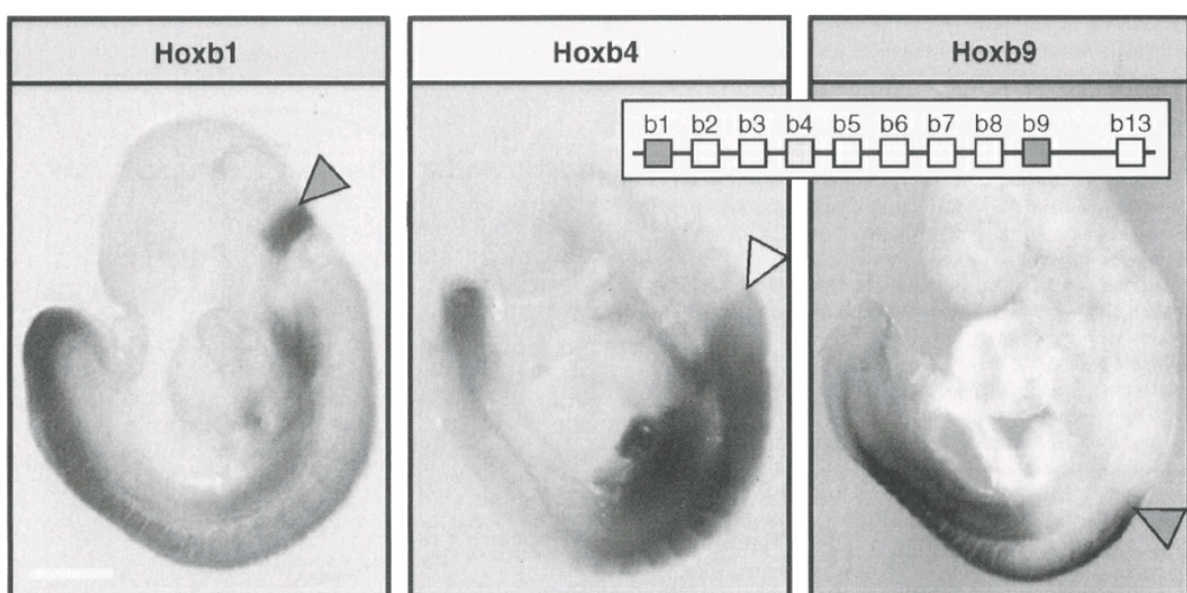
Finally, it is now well established that neurogenesis occurs in adults as well as in the prenatal period. New neurons have been identified that originate in the hippocampal subgranular zone and then migrate to the dentate gyrus, where they extend axons, and become functionally active (83).


FIGURE 3.3.1.6. Homeodomain-containing genes and their expression in the neural axis. Hox gene expression in the mouse embryo. The three panels show lateral views of 9.5-day-old mouse

embryos stained with antibodies specific for the protein products of *Hoxb1, Hoxb4,* and *Hoxb9* genes. (Adapted from Wolpert L, Beddington J, Brockes J, et al.: *Principles of Development*. Oxford, Oxford University Press, 103, 1998.)

Migration of Neurons and Microglia

The early embryonic development of the nervous system is characterized in part by the migration of populations of neurons and the immune cells of the brain, microglia. Examples of this phenomenon include the migration of neural crest cells to form elements of the peripheral nervous system (autonomic and sensory ganglia, glial cells, and adrenomedullary cells) and the migration of neurons born within the ventricular zone to their final destination within the cortical laminae. A range of factors mediate these events, and some have been identified, including proteins that contribute to inherent directional preferences, chemotaxis, and differential adhesion of cells as they migrate (84).

In the case of corticogenesis, it has been established that, as glutamatergic projection neurons are produced, they migrate along radial glial guides that stretch between the ventricular surface and outer cortical surface (85). Cytoskeletal proteins, molecular motors, and adhesion molecules are necessary for this migratory process to occur (86,87). One example is the extracellular glycoprotein reelin, which is secreted by interneurons in the outermost cortical and hippocampal marginal zone, and whose deficiency results in aberrant migratory patterns and layering of glutamate projection neurons in cerebral cortex and hippocampus (as is seen in the "reeler" mouse mutant) (88). Another example is the microtubule-binding protein doublecortin, which is selectively expressed by newly generated, migrating neurons. Cortical neurons are unable to complete their migration when doublecortin expression is decreased in mouse models (89) and in humans with doublecortin loss of function mutations. Inborn mutations in the doublecortin gene and other genes that govern neuronal migration have been implicated in a number of human disorders, including X-linked lissenencephaly, focal pachypolymicrogyria, and the "double-cortex" syndrome (90) (see Chapter 3.3.3). Isolated cortical dysplasia, which are patches of cortical neurons with abnormal layering, have been found in autism spectrum disorders (91). In many instances, the genes responsible for the abnormal migration have not yet been identified (92).

A second type of migration has been described, which is independent from radial glial cell guides, and involves the rapid "tangential" movement of GABAergic neurons from their site of origin in the medial, lateral, and caudal ganglionic eminences to the cerebral cortex, hippocampus, basal ganglia, and olfactory bulb (93,94). The gene Arx plays an important role in GABAergic progenitor migration and mutations of Arx are known to cause several different developmental brain

disorders including cortical dysplasia (95). An abnormal number and location of GABAergic cells in prefrontal regions of the cortex is considered the most replicated biologic abnormality in schizophrenia (96), and an abnormal distribution of GABAergic neurons has been also found in severe cases of Tourette syndrome and possibly other hyperactivity disorders (97,98). Hence, the regulation of tangential migration, which is the focus of considerable attention in current neuroscience research, may turn out to be of fundamental importance for the pathogenesis of common neuropsychiatric disorders.

Another important component of early developing brains are microglial cells. Microglial progenitors migrate after generation from myeloid precursors in the yolk sac to the embryonic neuroepithelium (99). Although microglia are the resident macrophages of the brain that are constantly scavenging the CNS for damaged neurons, plaques, and infectious agents, they also play an important role in neural circuit formation. Indeed, they have now been shown to express and secrete immune-related signaling molecules that alter synaptic transmission and plasticity even in the absence of inflammation (100). Furthermore, throughout life the microglia have been shown to respond to immune signals from the periphery and from within the brain leading to changes in the strength of synaptic connections between neurons, even altering the activity-dependent changes that are required for learning and memory. Remarkably, PET neuroimaging studies and postmortem human brain analyses have provided clear evidence for aberrant microglial activation in a number of disorders, including Tourette syndrome (101,102), and autism (103,104). Indeed there is mounting evidence that neuroinflammation may well play an important role in a number of developmental neuropsychiatric disorders including autism and schizophrenia (105).

Neural Connectivity and Survival

Developing nerve cells have the remarkable characteristic of being able to maintain contact with literally thousands of other nerve cells by extending cellular processes over substantial distances. These contacts are of crucial importance in establishing and maintaining the functional integrity of the nervous system. These processes initially develop by way of local extension and retraction of specialized areas on the surface of the neurons called growth cones. A variety of external signals regulate the formation, maintenance, and/or degradation of these neuronal connections, including mechanical guides, differential adhesiveness including interactions with astroglial cells, the influence of electrical fields, and interaction with gradients of trophic substances (84,106,107).

Once neuronal processes reach their target field, the neurons acquire obligatory trophic dependencies. Target fields contain growth factors such as nerve growth factor (NGF) that bind to the axons projecting to that field and are retrogradely

transported to the afferent cell body. A given target field, however, is able to support only a limited number of neurons, and the “extra” neurons are lost. For example, although NGF does not attract sensory nerve fibers to their target fields, it is intimately involved in the target-mediated survival of neurons. Indeed, from the first appearance of the neuronal processes in the target field, there is a marked increase in the rate of transcription of the NGF gene and the amount of NGF in the target field. There is also a rapid appearance of cell surface receptors for NGF on the sensory neurons (mediated by the transcription of the NGF receptor gene) (108).

Genetic factors are likely to play an important facilitatory role in neurite outgrowth and synaptogenesis throughout life. The dynamic equilibrium between neurite outgrowth and the formation of synapses versus neurite pruning and synapse withdrawal may well be a crucial mechanism that allows organisms to modify their behavior or “learn” as a result of experience. Although the precise genetic and molecular mechanisms that underlie these complex processes are not fully understood, one mechanism involves genes that code for molecules involved in neuronal communication. For example, in vitro and in vivo studies have indicated that neurotransmitters that are present in the early developing brain, such as GABA, in addition to their communicative function in mature neural systems, play important roles in the addition and pruning of neural processes and synapse formation (109). The ephrin family of genes is implicated in ensuring that there is accurate interconnectivity between similar topographic maps in different regions of the brain that neuronally represent the outside world (110). Microglia also monitor synaptic activity that leads to changes in neural circuits and the strength of synaptic connections. Indeed, many neurodevelopmental disorders, including Tourette syndrome and autism are associated with immature and anomalous neural circuits (111,112). A number of mouse mutants are also providing valuable insights into the genes, molecules, and mechanisms that mediate the connection of cortical neurons to other cortical and subcortical targets (113).

The Role of Early Life Experience

The development of the nervous system depends on environmental as well as genetic factors. At each level and stage of development, the micro- and macroenvironments of the organism play a crucial role, in part by modulating the epigenetic status of the cell. This means that our ability to separate out the relative contributions of genetic and epigenetic influences is difficult because the genes influence the environment through the production of various proteins and the environment, in turn, alters the expression of genes (Figure 3.3.1.7).

FIGURE 3.3.1.7. Gene–environment interactions. (Adapted from Purves D, Lichtrnan JW. *Principles of Neural Development*. Sunderland, MA, Sinauer, 1985.)

Environmental factors can certainly influence early developmental events. It is well established that drugs, alcohol, altered nutrition (including a lack of oxygen, or hypoxia), and infectious illnesses disrupt the orderly progression of neuronal growth during critical periods of brain development. The situation changes significantly during the latter part of gestation onward as the CNS becomes functionally active. A great deal of experimental evidence has indicated that neuronal activity, triggered by interactions of the organism with its environment, is required for the proliferation of these connections, as well as their later refinement (114,115). Hubel and Wiesel demonstrated that activity from both eyes was necessary to form the normal ocular dominance columns in visual cortex (116). Prior to and immediately following birth, inputs from the eyes make overlapping synaptic contacts in cortex. Through visual activity, there is a progressive segregation of the visual inputs from each eye into adjacent columns, a specific example of activity-dependent plasticity. Deprivation of vision from one eye during early postnatal development has been shown to result in

loss of normal vision from the deprived eye, because during this "critical" period, sensory input is crucial for development of visual cortex structure and function. Vision restored later may not be sufficient for a complete "catch-up" in development, and the failure to develop properly segregated columns becomes permanent (117).

While this has traditionally held in humans who did not experience normal visual inputs during their first years of life, such as infants born with either unilateral or bilateral cataracts, some recovery of visual function has now been documented with sufficient time/experience after vision restoration (118,119). However, the importance of early sensitive periods is still clear, since adults may have cataracts for years and regain visual acuity once they are removed.

Recent research has also suggested that development begins earlier than believed, with ocular dominance columns developing before any activity is detectable in the cortex (120). Hence, it appears that experience confirms or modifies rather than establishes cortical architecture. This activity-dependent refinement occurs in many regions of the cortex involved in sensory perception such as the remodeling of cortical regions after amputation of a finger (121). The earlier this occurs, the more plastic is the cortex in remodeling. Regions that used to subserve the amputated finger regress and nearby digits expand their representations into the region. An extreme example of neural plasticity and the capacity for the brain to reorganize connections involves the artificial rewiring of visual projections to the auditory cortex that allows the animal to "see" using its auditory cortex.

A different kind of critical period with distinct types of genetic regulation was discovered in the early 2000s concerning the role of maternal stimuli and pup–mother interactions in shaping the future behavior of the progeny (122). In animal studies, the level of maternal care as measured by licking and grooming by a mother profoundly influenced her female offspring to offer high or low levels of maternal care a generation later. It also established an enduring pattern of stress response in offspring as they matured. The pups raised with more licking showed less stress in response to novel environments (123). These findings are consistent with other studies that have documented the enduring impact of maternal stress in the perinatal period (124,125). Importantly, many of these effects appear to result from environmental effects on gene expression in limbic regions of the brain. For example, the level of care by the mother regulates the DNA methylation and histone acetylation of the glucocorticoid receptor gene promoter and the entire genome in rodents, non-human primates as well as in our species (126–128). These findings demonstrate that early epigenetic alterations in these neurobiologic systems may alter an individual's vulnerability to later psychopathology, including mood and affective disorders (129). These findings also point to the daunting complexity of neural development given that the epigenetic signatures seen in the periphery are not exactly the same as those seen in the CNS (127).

Finally, it is likely that events in early family life, interactions with peers, and

educational opportunities shape the course of development just as surely as the developing individual profoundly influences his or her environment. The developmental perspectives of child psychiatry echo in the study of developmental neurobiology.

FUTURE PROSPECTS

Genetics, epigenetics, and the developmental neurosciences are on the threshold of a new era in which we can study not only the sequence of the human genome but the entire sequenced genome of populations of individuals with particular disorders and even variations in genome and RNA sequences between their cells. This has been possible through astounding advances in molecular technology (130), dropping the price of sequencing a genome below $2,000 and heading still lower. We also have unprecedented tools now to manipulate genetics using silencing RNA constructs, molecular tools such as CRIPSRs and zinc finger nucleases that can produce gene knock outs without the use of transgenic technology (131), and even methods that can target the methylation to specific loci in the DNA (132). Using these tools, the genetic underpinning of neuropsychiatric syndromes can be explored (133,134), models of these diseases successfully created, and treatments based on understanding of their etiologies developed.

The human brain with its 100 billion neurons and its 100 trillion synapses is the most sophisticated computational machine known, about whose self-construction or function we know little. But one thing we do know is that events early in life matter, in part due to the complex layers of genetic and epigenetic influences upon patterns of gene expression. A deeper understanding of the impact of these mechanisms may also set the stage for preventative interventions in our field. One area worthy of pursuit is the refinement and implementation in a sustainable fashion of early childhood education and family support programs of proven value (135). It will also be important to study the mechanisms by which phenotypic traits can be inherited through male or female germlines, as this may well be unique form of adaptation that has occurred over the course of our evolutionary history (41).

Although the scientific, information management, and logistical challenges to understanding the complexity of the human genome vis-à-vis brain development are daunting, they are likely to pale in comparison to the ethical dilemmas to be faced as information about our genetic vulnerability becomes accessible. The ethical problems will multiply as even more potent pharmacologic tools are developed that can influence these developing neurobiologic systems. We also predict that this new knowledge will emphasize the importance of early life events in shaping the CNS and will point the way to the profound and enduring importance of selective early interventions for families at high risk (136,137).

CHAPTER 3.3.2 ■ ASSESSING RISK: GENE DISCOVERY

THOMAS V. FERNANDEZ, ABHA R. GUPTA, AND ELLEN J. HOFFMAN

INTRODUCTION

There is indisputable evidence for the heritability of most early-onset neuropsychiatric illnesses. However, most of the genes conferring risk for these disorders remain largely unknown. Up until approximately the last decade, the process of risk gene discovery had been surprisingly slow and frustrating, especially when considering the strength of the data regarding genetic contributions to childhood disorders. This, of course, was not for lack of effort, ingenuity, or determination on the part of patients, families, and researchers. However, the tide has been changing as technologic advancements have been the main driving force accelerating risk gene discovery. The advent of affordable, high-throughput genotyping (whole-genome microarrays) and massively parallel sequencing (whole-exome and whole-genome) over the last several years has revolutionized the field and is facilitating an ever increasing pace of progress. Furthermore, an extraordinary level of involvement by private foundations, parent and advocacy groups, research consortia, and broad interdisciplinary research efforts involving clinicians, geneticists, and neuroscientists has been transformational, allowing for large collections of patient biomaterials that are shared with the broader scientific community. This synergistic convergence of technology and collaborative efforts has ushered in an era of risk gene discovery in several common childhood neuropsychiatric disorders, including autism spectrum disorder (ASD), schizophrenia, and intellectual disabilities (ID). The pace of these discoveries has been accelerating, and they are beginning to deepen our understanding of the biology of these disorders. As work on this front continues, the potential for these insights to influence clinical practice and inform new treatments is coming into clearer focus.

In this chapter, we will address the general challenges to risk gene identification that have confounded investigations of childhood neuropsychiatric disorders, outline the major research strategies and technologic advances that are helping to overcome these obstacles, and discuss the use of animal and cell models to begin translation of genetic discoveries from “bench to bedside.” This discussion is intended to lay the groundwork for subsequent chapters, which will review more specific genetic findings relevant to individual disorders, describe the interplay of environment and genetics in conferring both risk and resilience, and highlight the potential contribution of genetics to research in the areas of psychopharmacology and neuroimaging.

OBSTACLES TO GENE DISCOVERY IN CHILDHOOD

OBSTACLES TO GENE DISCOVERY IN CHILDHOOD NEUROPSYCHIATRIC DISORDERS

Multiple Interacting Genes

Over the last four decades, the identification of disease-causing genes has become commonplace (1). These successes have largely been in the area of single gene disorders exhibiting Mendelian patterns of inheritance: that is, dominant, recessive, or X-linked (Table 3.3.2.1). In general, the inheritance of psychiatric disorders, such as schizophrenia, bipolar disorder, ASD, and Tourette disorder (TD) do not appear to fall into this category, in the sense that they cannot be accounted for by the transmission of a single gene. Rather, the commonly accepted view is that, for the most part, these disorders will be found to be the result of multiple interacting alleles, each with relatively small contributions, compared to the genetic effects observed in Mendelian disorders. For instance, in the case of ASD, analysis of linkage data, family studies, and more recent genome-wide genotyping and sequencing data has led to a hypothesis that as many as one thousand genes are likely to be involved (2).

Many psychiatric conditions are also strongly influenced by nongenetic factors. For instance, in the case of schizophrenia, the monozygotic concordance rate (Table 3.3.2.1) is approximately 50% (3,4). The observation that twins sharing all their genetic material share a diagnosis only half the time strongly suggests that influences apart from the sequence of their DNA are contributing to disease risk. These influences may be environmental in the classic sense, or may involve heritable genetic mechanisms that are not coded for in the sequence of DNA (epigenetic factors). The elaboration of the extent and nature of gene–environment interactions in developmental neuropsychiatric disorders is a vibrant area of research that has resulted in important recent insights into the etiopathology of mood, anxiety, psychotic, and attentional disorders, among others (5–7). These findings are reviewed in more detail in subsequent chapters.

An Uncertain Genetic Architecture

The combination of multigene inheritance, environmental, and epigenetic influences present significant challenges to researchers interested in gene identification. In addition, fundamental questions remain regarding the genetic architecture of nearly every childhood neuropsychiatric disorder. For instance, it is not known whether genetic variation that is common or rare in the population is likely to carry most of the risk for common childhood neuropsychiatric conditions. This issue is important for selecting appropriate research strategies to identify contributing genes as well as in interpreting the resulting findings.

Two alternatives are most commonly investigated. One is the "common disease-common variant" hypothesis, which holds that most of the risk for complex neuropsychiatric disorders will be accounted for by variations, or alleles, that are common in the population. By definition, these are genetic polymorphisms that are present in more than 1% of individuals. An often-cited early example is Alzheimer disease and the increased risk conferred by the e4 allele at the apolipoprotein E (APOE) gene locus, a variance that occurs with relatively high frequency in the general population (8,9). In the case of common disorders that begin late in life, it is widely accepted that common alleles are likely to play a major role. This is because natural selection is not likely to suppress variants whose effects occur after the age at which individuals typically reproduce. Hence, deleterious alleles contributing to late-onset conditions may attain a substantial frequency in the general population.

GLOSSARY OF SELECTED TERMS (COURTESY OF NATIONAL HUMAN GENOME RESEARCH INSTITUTE)

Term	Definition
Allele	One of the variant forms of a gene at a particular locus (gene location), on a particular chromosome. Different alleles may have functional significance or may be normal variants.
Association study	These studies examine the relative allele frequencies among populations with and without a phenotype of interest.
Candidate gene	A gene suspected of being involved in a disease, based on prior suggestive evidence. For example, the gene may be located within a region of a chromosome detected by linkage analysis, the gene's protein product may suggest that it could be associated with a disease, or the gene may be located near a chromosomal abnormality.
Chromosome	One of the thread-like "packages" of DNA in the nucleus of a cell. Humans normally have 23 pairs of chromosomes, with 22 pairs of autosomes and 1 pair of sex chromosomes. Each parent contributes one chromosome to each pair.
Complex disease	A disease caused by the interaction of multiple genes and environmental factors; they are also called multifactorial.
Copy number variation (CNV)	When the number of copies of a particular genetic region varies from one individual to the next. Gains and losses of genetic material.
Concordance	The presence of a given trait or phenotype in both members of a twin pair.
Deletion	A particular kind of mutation: Loss of a piece of DNA from a chromosome. Deletion of a gene or part of a gene can lead to a disease or abnormality, but can also be benign.
Dominant	A Mendelian pattern of inheritance in which a single transmitted gene variant results in a specific phenotypic characteristic, including, for example, a disease. Typically there is a strong relationship between carrying the genetic variant and having the disease. With a dominant gene, the chance of passing on the gene (and therefore the disease) to children is 50% in each pregnancy.
Duplication	An extra copy or copies of a chromosome segment.
Epigenetics	An emerging scientific field that studies heritable changes caused by the activation and deactivation of genes without any change in the underlying DNA sequence.
Exon	The region of a gene that contains the code for producing the gene's protein. Each exon codes for a specific portion of the complete protein.

Term	Definition
FISH	Fluorescence in situ hybridization. A technique that uses fluorescent probes that attach to unique known regions of chromosomes. It is useful for determining the location and extent of chromosomal abnormalities and for gene mapping.
Gene	The basic functional and physical unit of heredity passed from parent to offspring. Genes are pieces of DNA, and most genes contain the information for making a specific protein.
Genome	The complete sequence of DNA contained in an organism or a cell, which includes all chromosomes within the nucleus and the DNA in mitochondria.
Genome-wide association studies (GWAS)	An approach to associate specific genetic variations with particular diseases. The method involves scanning the genomes from many different people and looking for genetic markers that can be used to predict the presence of a disease.
Genotype	An individual's collection of genes, or the two alleles inherited for a particular gene. The genotype is expressed when the information encoded in the genes' DNA is used to make protein and RNA molecules. The expression of the genotype contributes to the individual's observable traits, called the phenotype
Insertion	A type of chromosomal abnormality in which a DNA sequence is inserted into a gene, likely disrupting the normal structure and function of that gene.
Intron	The region of a gene containing a sequence of DNA that does not code for the gene's protein product.
Linkage	The relationship between genes and/or markers that lie near each other on a chromosome. Linked genes and markers tend to be inherited together. A marker and a phenotype are linked when they are inherited together.
Linkage analysis	Statistical examination of the likelihood that markers are linked to a particular phenotype by tracing inheritance through families. A high likelihood of linkage (expressed as a LOD score) at a locus suggests that the variation causing or contributing to disease is near the marker(s) being investigated.
Locus	The location on a chromosome where a specific gene is located.
LOD score	Logarithm of the odds. A likelihood ratio that expresses the statistical evidence in favor of linkage.
Marker	A variable segment of DNA with an identifiable physical location on a chromosome and whose inheritance can be followed. Because DNA segments that lie near each other on a chromosome tend to be inherited together, markers are often used as an indirect means of tracking the inheritance pattern of a gene that has not yet been identified.
Mutation	A permanent structural alteration in DNA. DNA changes may have no effect, may cause harm, or may improve an organism's chance of surviving and passing this alteration on to descendants.
Phenotype	The observable traits or characteristics of an organism (hair color, weight, or the presence or absence of a disease). Phenotypic traits are not necessarily genetic.
Polymorphism	A common variation in the sequence of DNA among individuals, typically defined as frequency of 1% or greater; often used as genetic markers for association studies.
Recessive	A Mendelian pattern of inheritance in which two copies of a mutant gene, one from each parent, are necessary to cause a genetic disorder.
Sequencing	Determining the exact order of the base pairs in a segment of DNA.
SNPs	Single nucleotide polymorphisms. Variations at a single nucleotide that occur in human DNA at a frequency of approximately one every 1,000 bases. These variations can be used as markers to track inheritance in families and to analyze linkage with a phenotype. By definition an SNP with a population frequency of greater than 1% is defined as "common."
Translocation	Breakage and removal of a large segment of DNA from one chromosome, followed by the segment's attachment to a different chromosome. May be unbalanced (loss of DNA) or balanced (no loss of DNA).
Whole-exome sequencing	DNA sequencing that targets the exons (parts of genes that code for proteins) of all genes in the genome. The exome makes up about 1% of the genome.

(WES)	
Whole-genome sequencing (WGS)	DNA sequencing that targets the entire genome.
X-linked	A Mendelian pattern of inheritance in which a disease-gene variant is located on the X chromosome, often causing X-linked diseases to be seen preferentially in males or to have a more severe manifestation in males (due to the presence of one normal copy of the gene in females carrying two X chromosomes).

This same logic, with minor modifications, can be applied to early-onset disorders: if one presumes that such conditions result from a conspiracy of multiple genes and that each contributing genetic variant has a relatively small effect, selection against any individual allele may be weak, allowing disease-related variations to become common in the population (10–12). In addition, it is possible that certain ancient alleles may have historically conferred some selective advantage, and only more recently contributed to disease. This is thought to be the case with respect to the identification of a common genetic variant associated with both childhood and adult-onset obesity (13). One can imagine that a gene allele predisposing to higher body mass index could have previously been advantageous during times of scarcity, and that relatively recent environmental changes would have transformed this into a genetic risk.

The common disease-common variant hypothesis is also consistent with what is known about the overall structure of the normal human genome (14). The majority of overall variation within a population is accounted for by common alleles. It would follow then that if selective pressure does not act to limit the frequency of incrementally contributing loci, common diseases would reflect this underlying structure, that is, common variation would account for common disease.

An alternate possibility is that a significant proportion of early-onset childhood neuropsychiatric disorders may be the result of rare genetic variation. This could occur via several scenarios: either through the accumulation of many different rare mutations within one or a small number of genes (allelic heterogeneity), or rare mutations in any of a large number of genes resulting in a similar or overlapping phenotype (locus heterogeneity). Moreover, these two mechanisms, locus and allelic heterogeneity, could combine within what is now considered a single psychiatric syndrome, a scenario which would present significant challenges to progress in genetic research.

The rare variant hypothesis is intuitively attractive, particularly in the case of severe early-onset illnesses. One could imagine that a genetic variation contributing to fundamental impairments in social functioning arising early in life could be subject to selective pressures, as affected individuals might be less likely to have offspring than those who are unaffected. If one looks to other areas of medicine for clues, and from what we have learned so far from the most studied psychiatric disorders, it is

most likely that a combination of rare and common variants plays a role in child psychiatric illness. For instance, in the case of ASD, rare alleles carrying significant disease risks have been identified. However, these mutations do not appear to account for the majority of population risk. Nonetheless, the discovery of rare alleles has provided vitally important insights into the pathophysiology of ASD (REFS).

The question of whether childhood neuropsychiatric disorders involve common or rare genetic variation is relevant because those methods and study designs that may be most appropriate to identify the contribution of one type of risk may have less power to identify the other (Figure 3.3.2.1). However, as sequencing technologies are advancing and costs are declining, research designs have been gradually turning toward comprehensively gathering data on both common and rare variation throughout the genome. This will be discussed further as the various approaches to gene hunting are presented below.
FIGURE 3.3.2.1. Allele frequency, effect size, and detection methods. (*Reproduced from State & Levitt, 2011, Nature Neuroscience 14, 1499–1506, doi:10.1038/nn.2924.*) Rare mutations have been found to carry larger effects than common variants. Linkage and association sections show typical approaches to demonstrating the role of rare versus common variation in

disease. Relationships between rare alleles and a phenotype are often demonstrated using linkage analyses; common variant relationships are usually demonstrated using association (case–control) methods. The shaded area shows the approximate range of effect sizes seen for rare alleles identified in ASD.

Phenotypic Heterogeneity

In addition to the obstacles presented by complex inheritance and an uncertain genetic architecture, diagnostic issues in childhood neuropsychiatric disorders present major challenges to geneticists. Ultimately, irrespective of the specific methodology employed, disease-gene hunting involves identifying observable clinical phenomena that bring together individuals with some degree of shared genetic risk and then uncovering the responsible or contributing variants within the genome. If one has difficulty identifying a group of affected individuals who share a proportion of their risk in common, gene identification can be quite difficult.

The absence of reliable and specific physiologic markers for childhood neuropsychiatric illnesses presents a significant challenge. Of course, one problem is that our current diagnostic approaches may have weak correlations with underlying biologic mechanisms. It is not yet possible to determine, for instance, whether similar genetic liabilities may underlie several diagnostic categories that are considered as quite separate within the boundaries imposed by current systems of classification (15). The high frequency of comorbidities and wide-ranging clinical presentations seen in childhood neuropsychiatric syndromes certainly suggest that this may be the case. New guidelines for categorizing research subjects with neuropsychiatric symptoms have recently been proposed and adopted by national research funding institutes in an attempt to alleviate this obstacle (16). In addition, while severe forms of any disorder may be quite easily recognized, more subtle manifestations may be difficult to assess and verify. The unambiguous delineation of affected versus unaffected individuals, even within an extended family, can also be complicated by clinical phenomena that change through the course of development, either through an age-dependent onset, a waxing and waning course, or symptoms that decrease markedly in adulthood.

The issue of diagnostic uncertainty in child psychiatry can also pose significant logistical problems in that it can be quite difficult to ascertain comparable samples across sites that are geographically remote. For example, in the case of hypertension, large-scale studies of individuals may be undertaken in which the diagnostic measures may involve little more than multiple readings from a blood pressure cuff. Contrast this with what is typically required for a state-of-the-art diagnosis in almost any psychiatric disorder. One can imagine that the effort and expense required to collect useful data on large numbers of patients in child psychiatry is considerably

more challenging than in many other fields of medicine.

APPROACHES TO GENE DISCOVERY AND CHARACTERIZATION

Assessing Heritability and Patterns of Transmission

Most often, gene discovery efforts are preceded by epidemiologic investigations aimed at determining the general nature and extent of the genetic risk. Such studies typically seek to identify whether a particular disorder aggregates within families and, if so, whether there is an identifiable pattern of transmission. This can be useful to identify whether genes might be involved. Moreover, a comparison of this risk among different degrees of relatedness may provide a clue as to the nature of the genetic transmission (17,18).

However, such investigations typically cannot determine whether the observed familial aggregation or increased risk is the direct result of genetic influences. In this regard, both twin and adoption studies play a critical role in teasing apart the relative contribution of genetic factors versus environmental factors in disease etiology. For twin studies, the rates at which monozygotic twins (MZ) share a diagnosis are compared to the rates for dizygotic twins (DZ). An assumption is made that both types of same-sex twins will have a similar degree of shared environmental influences. Consequently, if genes "trump" environment in the etiology of a disorder, those siblings that share all of their DNA (MZ) should be more likely to share a diagnosis than twins who share the same amount of DNA as any sibling pair (DZ). Conversely, if environment predominates as a contributing factor, rates of concordance should not fundamentally differ based on the amount of shared genetic material. Adoption studies accomplish a similar goal by comparing monozygotic twins who are raised together versus those in which twins are raised apart. These types of investigations are quite powerful, but are less common in the literature than twin studies.

For ASD, MZ concordance has been found to be in the neighborhood of 60% for the full syndrome and 90% for the broad spectrum. In contrast, DZ concordance has been found to be relatively low, about 3% to 15%, depending on the diagnostic criteria employed. These data support the conclusion that the observed familial clustering is largely the result of genetic factors and translate into an estimate of heritability that places ASDs among the most strongly genetic of all neuropsychiatric conditions (2,19).

Once family, twin, and adoption studies have demonstrated that genetic factors are likely to play a role in the pathogenesis of a disorder, there are several different means to identify the specific genes involved: linkage analysis, including whole-genome screens in affected sibling pairs; gene association studies, including

candidate gene studies, family-based studies of association, and genome-wide association studies (GWAS); molecular cytogenetic methods, including karyotyping, fluorescence in situ hybridization (FISH), and microarray comparative genomic hybridization (CGH); and high-throughput next-generation sequencing (NGS), including whole-exome and whole-genome sequencing. We will next examine the basic principles behind these methods, as well as advantages and pitfalls of each as they relate to the search for susceptibility genes in child psychiatric disorders.

Linkage Analysis

Linkage analysis assesses the probability that a given phenotype and a particular genetic marker (or series of markers) are transmitted together from one generation to another (Figure 3.3.2.2A). This method is based on the principle that, within affected families, genetic loci associated with a disorder are transmitted from parents to children more often than would be expected by chance (20). Results are expressed as a logarithm of the odds (LOD) score, such that, for example, an LOD score of 3 indicates the odds in favor of linkage between a marker and the disease are 1,000 (10^3):1. Indeed, this particular score is taken as the threshold for statistical significance in an investigation of the whole genome, due to the fact that multiple comparisons are conducted (one simultaneously investigates multiple markers). For a parametric analysis, in which one specifies a hypothesis about the nature of the proposed genetic transmission (e.g., that a disorder is the result of a dominantly acting mutation that is rare in the population), 1,000:1 odds in favor of linkage at a marker (LOD score of 3) roughly corresponds to a genome-wide p value of 0.05.
FIGURE 3.3.2.2. Schematic illustrations of linkage and association principles. **A:** Linkage analysis. A pedigree showing disease (*solid shade*) among males (*squares*) and females (*circles*) in multiple generations. The pair of numbers under each member of the pedigree represents the alleles of a DNA marker which was used to genotype the family. By analyzing the pattern of affected status within pedigrees, one may hypothesize the pattern of disease inheritance (dominant in this case) and then use a parametric linkage approach. By analyzing the frequency with which a particular genotype occurs along with disease in one or multiple families, it may be possible to conclude that a gene involved in disease phenotype is likely to lie in close proximity to a DNA marker. In this case, grandmaternal marker allele 2 appears to be linked to disease. **B:** Association studies. Individuals with a particular disorder or phenotype (*labeled A*) are compared with

control subjects without the disease or phenotype (*labeled B*) to determine whether one group is more likely to carry particular allele(s) of the gene(s) being studied.

There was initially great optimism in the potential of linkage analysis to uncover genes for neuropsychiatric illnesses, based on a host of dramatic discoveries, including the identification of genes for Huntington disease, hypertension, ID, and various cancers (1,21,22). However, early returns in several areas of child psychiatry were not as rewarding as anticipated. For instance, with respect to TD, when early parametric linkage studies did not identify TD-related loci, an international genetics consortium turned to nonparametric approaches. Several such studies have been reported in TD (23–27), with several "hits" approaching genome-wide statistical significance in individual studies (defined as a LOD score of 3.6). However, independent studies have not converged on any genomic region. Similarly, linkage analysis efforts in schizophrenia (28–33) and ADHD (34–39) have shown little overlap and poor replication, although several loci containing potential candidate genes have been reported for some disorders, such as dyslexia (40).

In retrospect, linkage studies have been most successful in identifying loci associated with Mendelian disorders. For genetically heterogeneous neuropsychiatric disorders, success has been limited when looking across families. Reasons for this include locus and allelic heterogeneity, differing inclusion criteria, and low statistical power, given the relatively small sample collections studied to date. Studies in other complex disorders in psychiatry and across medicine suggest that robust identification of risk alleles in nonparametric linkage analyses is likely to require cohorts of many thousands of patients (41). An alternate and perhaps more promising approach to complex disorders is linkage analysis within single pedigrees that display a clear pattern of inheritance and include multiple affected members. Such families can be difficult to identify and the risk alleles they carry may be rare, yet linkage analysis can offer unique insights into biologic mechanisms that can cause the disorder.

One example of single pedigree linkage analysis leading to a novel understanding of disease pathogenesis and a potential new treatment target can be found in TD. In 2010, Ercan-Sencicek et al. (42) described a two-generation pedigree in which a father and all eight of his children had TD, a pattern suggestive of a single dominant allele of large effect size in this family. Parametric analysis identified a single region on chromosome 15 yielding the maximum theoretically possible LOD score for the pedigree. Sequencing of the 55 genes in this region led to the identification of a nonsense point mutation (W317X) in the gene *histidine decarboxylase* (*HDC*). *HDC* encodes the enzyme required for the synthesis of histamine from histidine, and in vitro studies showed the nonsense mutation completely abolished its biosynthetic function (Figure 3.3.2.3).

This study represented the first association of disrupted histamine biosynthesis with TD (43). While this particular mutation has not been found in any other individual (affected or unaffected) to date, subsequent studies of copy number variation (CNV) in TD (44) and modeling HDC disruption in an animal system (45–47) support a role for histamine in TD biology and have led to a clinical trial of a histamine-targeting pharmaceutical, the histamine H3 receptor antagonist AZD5213 (ClinicalTrials.gov Identifier: NCT01904773). This relatively rapid progress, moving from a single index family to a new mechanism and potential new treatment, demonstrates the utility of linkage analysis in particular families as well as the more general promise of using genetic findings as an entry point into a translational science pipeline that will lead to a better understanding of disease biology and novel treatments (Figure 3.3.2.4).

Association Analysis

In contrast to linkage studies, which examine transmission within families, association studies assess gene frequencies within populations. The first association studies typically investigated one or a number of known, common genetic polymorphisms (markers) in or near predetermined candidate genes of interest. In essence, the methodology is a variation on the classic case–control design. In general, in the field of human genetics, one seeks to determine if individuals with a particular disorder or phenotype are significantly more (or less) likely than controls to carry particular allele(s) of the gene or genes being studied (Figure 3.3.2.2B).

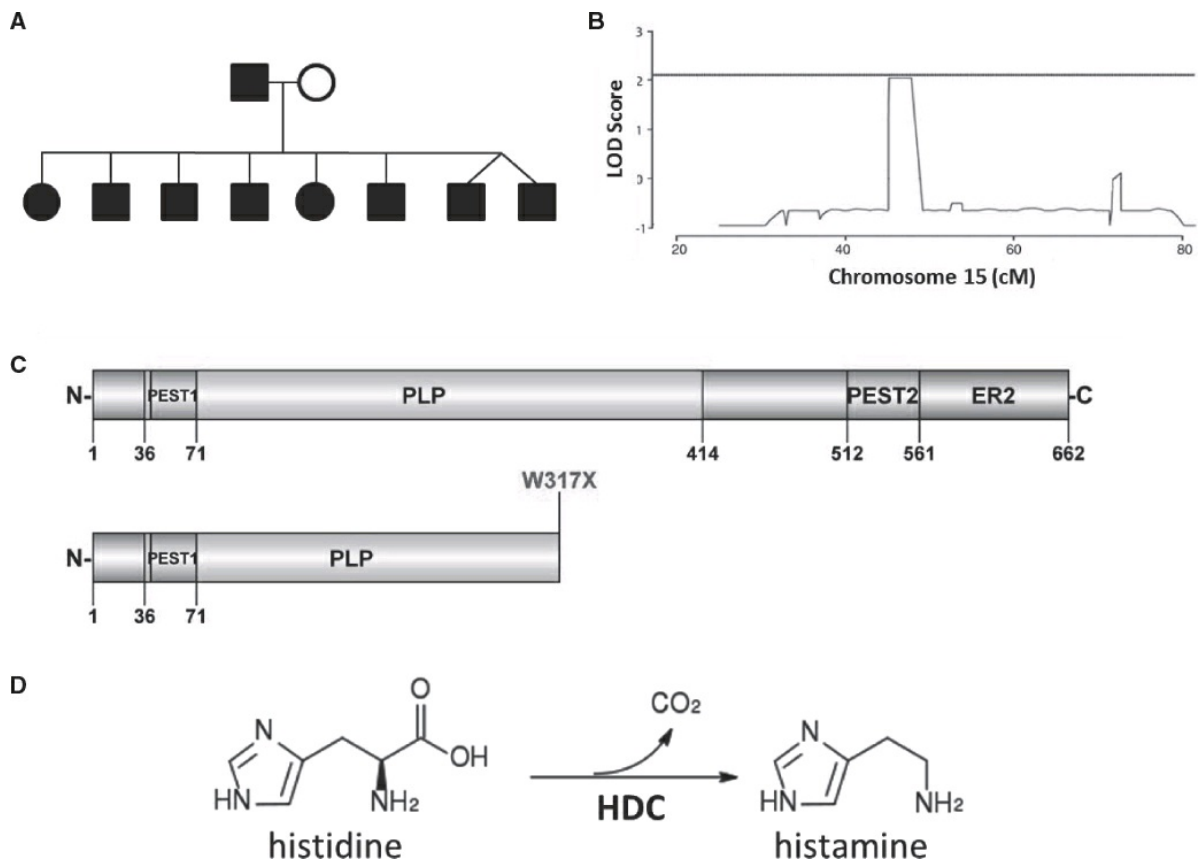
Association methods have been shown to be more powerful than linkage methods under a number of conditions that typically prevail in complex disease. In particular, they are considered to be more powerful in detecting common susceptibility variants of relatively small effect, unlike linkage analysis, which requires relatively strong genetic effects given feasible sample sizes (15,48–50). Association studies are also popular for practical reasons. The most commonly used designs study either affected individuals versus unrelated controls, or as is often the case in pediatric disorders, affected probands and their parents (where the nontransmitted parental alleles are used as the control). This contrasts with parametric linkage analyses, in which extended families must be identified and characterized, or nonparametric linkage studies that often require the identification of two affected siblings, thus excluding a significant number of patients who present to clinic. As a result, association studies make the study of large numbers of subjects reasonably practical and often allow this type of investigation to dovetail with other case–control studies being conducted simultaneously, such as pharmacologic studies.


FIGURE 3.3.2.3. Linkage analysis of an outlier pedigree identifies a mutation in *HDC*. (*Reproduced from Tourette Syndrome. Davide Martino and James F. Leckman, Editors Oxford University Press*.) **A:** Two-generation pedigree with 9 TD affected individuals (*solid symbols*). **B:** Parametric linkage LOD scores along a section of chromosome 15. The horizontal line indicates the maximum theoretical LOD score (2.1) for this family. **C:** All affected family members carry a nonsense mutation affecting the *HDC* gene transcript. The wild-type HDC protein (**top**) contains 662 amino acids; the mutant HDC protein (**bottom**) is predicted to be truncated at the site of the W317X mutation. **D:** The HDC protein (L-histidine decarboxylase) is the rate-limiting enzyme in histamine biosynthesis. See (42).

For many years, candidate gene association studies were popular across all fields of medicine due to the ease and low cost of genotyping a small number of variants. Furthermore, the required number of statistical comparisons was low, allowing nominal statistical significance to be achieved using relatively small cohorts. However, as genomic tools have advanced and more robust approaches (reviewed below) have largely replaced candidate gene studies, several important weaknesses have come into focus, which can explain why such studies have been largely unsuccessful in yielding significant reproducible findings for complex disorders. First, the genetic markers or SNPs used in these studies are preselected based on

existing pathophysiologic hypotheses; given the presence of millions of SNPs and our limited understanding of disease mechanisms, there is a very low prior probability that any selected marker will be associated with the disorder (41,51). Furthermore, even if the correct genes are selected, the specific markers interrogated may not be adequately linked to the specific variants that influence disease risk.

A second important limitation of association studies is their vulnerability to false-positive results (52). One source of this error may be population stratification. This results from variations in the frequencies of certain genetic markers among different ethnic groups. If one compares individuals with a particular phenotype to controls, and the two groups are not ethnically similar, a genetic marker that is found more frequently in the affected group will erroneously appear to be associated with the identified phenotype. In retrospect, many candidate gene association studies have failed to adequately control for population stratification, and precise matching is essential for reliable and reproducible results. Finally, based on the small effect sizes expected for common alleles contributing to most common disorders, very large cohort sizes are required for reliable gene discovery; it is clear that the candidate gene association studies reported to date for almost all neuropsychiatric disorders have employed sample sizes that are far too small.

Genome-Wide Association Studies

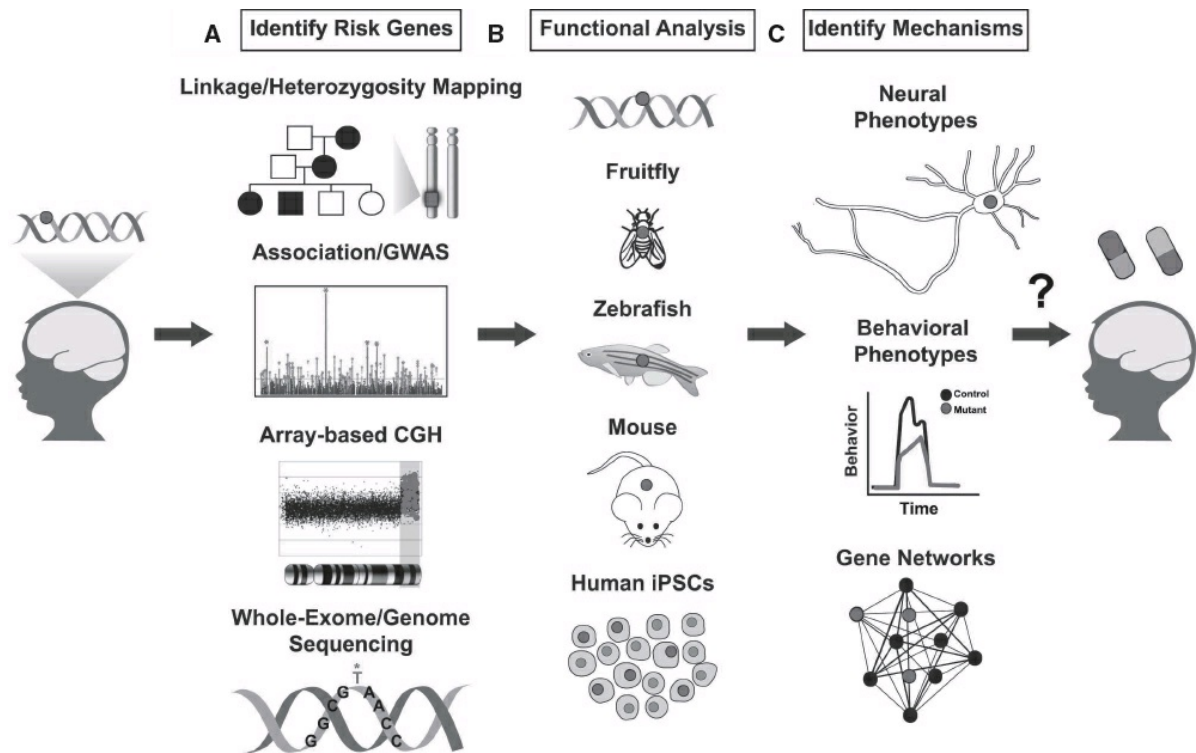
Due to the limitations described above, there has been a shift in methodology from candidate gene association to studies of genome-wide association, simultaneously testing hundreds of thousands to millions of common SNPs for association with complex disorders. This movement toward GWAS coincided with advances in microarray technologies that delivered affordable high-density genotyping platforms. Querying genetic markers throughout the genome eliminates the need to identify candidate variants a priori and allows hypothesis-neutral investigations. This method also yields data that allows rigorous matching for ancestry between cases and controls, an aforementioned confounder in earlier association studies. The primary challenge in GWAS is the large number of independent comparisons performed, requiring a widely accepted genome-wide significance threshold of $p \leq 5 \times 10^{-8}$. Given the heterogeneity of complex disease, large sample sizes are required to achieve this level of significance. Nevertheless, this technique has led to renewed excitement in the field, with somewhat mixed results to date for complex neuropsychiatric disorders.


FIGURE 3.3.2.4. Schematic representation of the identification and functional analysis of risk genes in childhood neuropsychiatric disorders. **A:** Risk genes (*circle* in DNA strand) associated with childhood neuropsychiatric disorders are identified in human genetics studies using multiple methods discussed in this chapter: linkage; genome-wide association studies (GWAS); array-based comparative genomic hybridization (CGH); and whole-exome and whole-genome sequencing. (Manhattan plot adapted from www.nimh.nih.gov) **B:** Functional analysis of risk genes is conducted using in vivo and in vitro approaches. These include: nonhuman animal model systems, such as *Drosophila* (fruit fly), zebrafish, and mouse; and human induced pluripotent stem cells (iPSCs). **C:** Functional analyses using the methods shown in (**B**) are used to identify biologic mechanisms and convergent pathways by examining a range of phenotypes resulting from risk gene loss, some of which are shown here, including neuroanatomical, cellular, physiologic, behavioral, circuit-level, gene expression, and gene network phenotypes. By revealing novel mechanisms, the functional analysis of risk genes has the potential to identify novel pharmacologic targets for childhood neuropsychiatric disorders.

For example, in ASD, none of the candidate genes emerging from earlier association or linkage studies have reached the threshold for genome-wide significance using GWAS (53,54), suggesting either that these candidate genes had initial false-positive associations or that the current GWAS lacks sufficient statistical

power to detect common variant association. Indeed, a GWAS study of schizophrenia from the Psychiatric Genomics Consortium (PGC) demonstrates that much larger sample sizes (>10,000 subjects) are required for the detection of variants reaching genome-wide significance (55). This study reported an association between schizophrenia risk and genetic markers across the major histocompatibility complex (MHC). More recently, data from the Schizophrenia Working Group of the PGC advanced this finding by showing that SNPs in complement component (C4) alleles are associated with schizophrenia and that these alleles lead to altered expression of C4 in the brain, leading to putative increased synapse elimination in brains of individuals with schizophrenia (56). In this way, results from GWAS can help to pinpoint susceptibility loci as well as begin to further our understanding of biologic mechanisms underlying disease.

Chromosomal Alterations

Another method for identifying risk loci contributing to complex disease in individual patients is to examine genomic regions affected by chromosomal abnormalities (e.g., deletions, duplications, translocations, inversions) in affected individuals and then identify genes in this region that may be disrupted as a result. These studies were most popular prior to the era of high resolution genome-wide investigations and involved using cytogenetic techniques such as karyotyping and FISH to map de novo chromosomal alterations. Because these types of findings derive from only one or a few patients, replication of the implicated loci is essential to establish that the findings are pathogenic.

This approach has been used successfully to identify the genes for multiple medical disorders (1) as well as a host of ID syndromes (22). For complex childhood neuropsychiatric disorders, it is assumed that genes affected by such rare gross chromosomal abnormalities are unlikely to account for any significant portion of susceptibility risk in most of the overall affected population. However, identifying genes involved in these rearrangements may identify loci that are mutated in affected but cytogenetically normal individuals or identify genetic pathways providing insights into the pathogenesis of more common forms of these disorders.
FIGURE 3.3.2.5. Using FISH to map a chromosome 13 inversion in a patient with TS. **A:** Photograph of metaphase chromosomes under 100× objective lens after hybridization with a fluorescent-labeled probe specific for a DNA sequence at 13q31.1. The experimental probe is visualized at the expected position on the normal (nl) chromosome 13. Two fluorescence signals are visible on the inverted (inv) chromosome 13, indicating that this probe spans the breakpoint. **B:** Illustration of how the chromosome 13 inversion results in two fluorescence signals when the DNA probe spans one of the inversion breakpoints. In this case, the breakpoint at 13q31.1 mapped near the gene SLITRK1 and further investigation of its sequence revealed rare mutations in three unrelated individuals affected with TS.

One illustrative example pointing to the potential value of this approach in common complex psychiatric disorders involves TD. Abelson et al. (57) studied a de novo chromosomal inversion in the only member of a family affected with TD (Figure 3.3.2.5). One of the two breakpoints identified in this child mapped near a gene known as *SLIT and Trk-Like family member 1* (*SLITRK1*). The other three genes mapping closest to the two breakpoints were thought to be less likely candidates, in part because *SLITRK1* was the only one known in the group to be expressed in brain regions thought relevant to TD and related disorders.

Given a starting hypothesis that mutations in *SLITRK1* would likely be rare among individuals with TD, the authors directly queried the entire coding and regulatory regions of *SLITRK1* among unrelated affected individuals. They identified a mutation in a second family with TD and related disorders that was predicted to lead to a truncation of the resulting protein, and which was not present in several thousand control individuals. Additional screening also demonstrated a rare variant in a regulatory region of *SLITRK1* that was present in two unrelated affected individuals and absent in several thousand unrelated controls, indicating a significant association (57).

The function of *SLITRK1* is not well understood. It is broadly expressed during

development and may have a role in axon pathfinding. Expression is greatly reduced in adulthood, though it persists in cholinergic neurons of the striatum (58). In vitro, overexpression of *SLITRK1* in cortical neurons promotes dendritic growth, while the TD-associated alleles lead to dendritic regression (57). A mouse knockout of *SLITRK1* exhibits anxiety and increased noradrenergic activity that is attenuated by the alpha-2 adrenergic receptor agonist clonidine (59), recapitulating some characteristics of TD (60,61). However, no tic-like movements were documented. Mouse knockouts of a closely related gene, *SLITRK5,* were found to exhibit excessive grooming, anxiety, and altered dendritic morphology in the striatum (62).

Subsequent examinations of the association of *SLITRK1* alleles with TD have produced inconsistent results, which is to be expected in studies of rare variation in samples of modest size. Resequencing of several hundred TD probands did not identify any additional coding mutations (63–65). In trichotillomania (66) and OCD (67), on the other hand, several rare missense mutations have been identified; the functional significance of these remains unclear. Associations with common variants have been reported in a small candidate gene association study (68) and in a subsequent haplotype analysis of 376 families with a TD proband (69). However, no SNPs within or near *SLITRK1*—including those examined in these common variant studies (68,69)—emerged as even nominally significant in the first TD GWAS study (70). This does not, however, rule out the possibility that the reported mutations in *SLITRK1* are causal, but rare.

The initial work by Abelson et al. identifying *SLITRK1* mutations in TD demonstrated both the important strengths as well as the potential weaknesses of the molecular cytogenetic approach. On the positive side, the work was able to identify both a specific candidate disease gene as well as specific functional genetic changes for further investigation. The study also demonstrated the liabilities of searching for rare genetic variants in a common disease. By definition, the results are likely to affect only a small number of individuals and no single piece of evidence may be a "smoking gun." The ultimate implications of the work can only come into focus through the identification of additional rare families with clear mutations in this gene, the elaboration of a biologic pathway including other genes that may carry risk for TD, and through further study of animal and cellular models (reviewed below), which may offer more clues regarding the relationship of *SLITRK1* to TD and related disorders.

Copy Number Variation

Over the last decade, advancements in microarray technologies have permitted detection of submicroscopic structural variation. These deletions and duplications of blocks of DNA throughout the human genome—called CNV when their length is at least 1 kilobase (kb)—are common both in the clinical and the general population

(71–74) (Figure 3.3.2.6). CNVs may encompass a single part of a gene, an entire gene, or multiple genes. Screening for large CNVs, both inherited and de novo, has proven an efficient strategy for detecting mutations potentially contributing to risk due to their rarity in the genome (75,76). Studies in schizophrenia (77–83) and ASD (84–88) have revealed an increased burden of rare CNVs, particularly genic de novo variants, in these disorders (80,84,85,89,90). For ASD, CNV detection using SNP genotyping arrays in >4,500 families has led to the identification of dozens of specific risk loci via recurrent de novo CNVs at 16p11.2, 7q11.23 (del), 15q12 (del), and 1q21.1, among other regions (84,89–93). Through integrative analyses of de novo CNV mutations in ASD, it is estimated that more than 200 risk loci are vulnerable to such mutations (90). Furthermore, when considered together, ASD-associated genes from CNV studies appear to cluster into networks enriched for neuronal synaptic function and chromatin regulation (90,93). These studies in ASD demonstrate the utility of CNVs to identify risk loci and provide further insights into the underlying biology and genomic architecture of complex disorders.
FIGURE 3.3.2.6. Schematic representation of copy number variant analysis. (*Reproduced from Hoffman EJ, State MW, J Am Acad Child Adolesc Psychiatry 49:736–751, 2010.*) One common approach to CNV analysis that can detect millions of SNPs using a microarray is shown here. First, genomic DNA is fragmented, denatured, and applied to a SNP microarray. Each microarray position contains beads (A and B) attached to a short DNA

sequence found in the human genome. Genomic DNA binds to these short sequences, which end before a known SNP. A fluorescent-labeled nucleotide is added to the end of each sequence in the presence of a DNA polymerase enzyme, based on which SNP is present in that location in the particular individual. Next, an informatics-based analysis is used to identify the presence of a CNV. Specifically, the relative amount of DNA at a particular location (log R ratio) in the individual being tested compared to a control population is determined, along with a measurement of whether an individual is heterozygous or homozygous for a particular SNP (B allele frequency). For example, the B allele frequency for AA, AB, and BB genotypes are 0, 0.5, and 1, respectively. If a deletion is present, the log R ratio is negative and the region appears homozygous, such that the B allele frequency is 1 or 0. If a duplication is present, the log R ratio is positive and the B allele frequencies are between 0 and 1 (e.g., if three copies of a region are present, the possible genotypes are AAA, AAB, ABB, and BBB, and the respective B allele frequencies are 0, 0.33, 0.66, and 1). This method allows for an assessment of the presence of CNVs in an individual throughout the genome.

High-Throughput, Next-Generation Sequencing

In recent years, DNA sequencing technologies have advanced tremendously. In contrast to Sanger sequencing, a long-standing method of reading the individual base letters of the genetic code developed in the 1970s, next-generation sequencing (NGS, also referred to as high-throughput, massively parallel, or deep sequencing) has revolutionized genomic research. NGS allows millions of small fragments of DNA to be sequenced in parallel, then uses bioinformatic analyses to reassemble these fragments by mapping the individual reads onto the reference human genome. This methodology dramatically accelerates the sequencing process, allowing an entire human genome (~3 billion base pairs) to be sequenced in about a day, although one can also use these methods to sequence just the coding regions of the genome, referred to as the exome (~1.5% of the genome) or particular targeted regions. Furthermore, due to target amplification, fragmentation, and parallel sequencing, NGS sequences each targeted region multiple times, providing high coverage of most regions (Figure 3.3.2.7). This high (or deep) coverage allows more accurate detection of genomic variants that might otherwise be missed with fewer sequence reads. It also allows for detection of a broader spectrum of mutations (e.g., CNVs) than is possible with traditional Sanger sequencing.

Whole-exome sequencing (WES) was first used for clinical diagnosis in 2009

(94) and it is now common in clinical use (95–97). One particularly fruitful use of sequencing data for gene discovery has been the search for protein-altering de novo SNVs and indels that occur in the same gene in more than one unrelated individual. Because de novo mutations are rare and often lead to changes with large effect size, recurrent mutations can signal high-confidence risk genes. This approach has been especially successful in the search for ASD genes (90,98,99); dozens of genes have been implicated without the need for prior hypotheses, which had been the hallmark of less successful candidate gene association studies. Furthermore, the identification of risk genes in this manner facilitates systems analyses that seek to discover the way in which these genes may coalesce within common biologic pathways and gene networks and reveal the important underlying neurobiology of disease (90,98,100).

FIGURE 3.3.2.7 Alignment representation of next-generation sequencing reads. Blocks represent particular nucleotides (A, C, T, or G) at that position. The width of each block is proportional to the quality score of the base. The first row is the reference human genome sequence that is expected. Subsequent rows are the sequencing reads that have been aligned to the human genome sequence. The vertical axis represents the number of reads (or depth) at each location. In this example, a heterozygous C/T single nucleotide variant (SNV) is detected on chromosome 2 at position 216246988 (within the gene *FN1*).

While there are still discoveries to be made by WES, the ENCODE project has demonstrated the importance of intergenic regulatory regions (101), leading to the realization that sequencing regions outside the exome will be necessary to identify all important genetic variants. Sequencing the complete genome of individuals is more data intensive and expensive than WES, but advancements in sequencing technologies and market competition has facilitated dramatic decreases in sequencing costs over the last few years (Figure 3.3.2.8), which now makes whole-genome sequencing (WGS) a more realistic endeavor for many laboratories. Early studies of WGS in

ASD are indicating that interrogation of regulatory regions outside of the exome will lead to discoveries that will help explain additional disease risk (102,103), positioning WGS as a promising tool to further our understanding of complex genetic disorders.

TRANSLATING GENE DISCOVERY FROM BENCH TO BEDSIDE

Animal Modeling

As the technology for identifying risk genes in childhood neuropsychiatric disorders continues to improve, there is an increased need to develop systems to progress from risk gene discovery to the identification of biologic mechanisms and pharmacologic targets. Given the expanding list of susceptibility genes associated with these disorders, such as ASD, the field of human genetics is approaching a bottleneck where the rate of ascertaining risk variants is beginning to exceed the ability to interpret their biologic significance. For this reason, after confirming the association of a gene with a particular disorder, a critical next step is modeling its function in a biologic system. The objective of such a system is to elucidate how disruption of a risk gene leads to the alteration of specific neuronal populations or neural circuits at defined stages of development, predisposing to behavioral dysfunction. In this way, these studies aim to illuminate the pathophysiology of childhood neuropsychiatric disorders, which remains incompletely understood, and to provide a path forward from risk gene identification to the discovery of biologic mechanisms and potential targets for pharmacologic treatments (Figure 3.3.2.4).

Model systems typically include either in vitro approaches, such as human induced pluripotent stem cells (iPSCs) (discussed in detail in the section, Stem Cell Modeling), or in vivo models, such as nonhuman animal systems, which may include a range of organisms from mouse to fish to fly. While there are benefits of in vitro methods, including the ability to study risk genes in human cells, animal models offer several key advantages. First, animal models provide a means of assessing the effect of risk gene disruption on the establishment of neural circuits in a live, behaving organism (104). In particular, the development of novel technologies for imaging neuronal activity in vivo has the potential to bridge the gap between gene and circuit function. Second, animal models are optimal for studying the role of a gene over time in an intact, developing nervous system (105), which is highly relevant to childhood neuropsychiatric disorders. Third, animal models can be used to identify novel pharmacologic targets and to conduct initial assessments of their potential to reverse structural or behavioral phenotypes resulting from risk gene loss (104). With respect to pharmacologic screens, both in vitro and in vivo methods may occur in parallel and complement each other, providing information on the effects of novel compounds

on cellular and circuit-level phenotypes identified in human cell culture and animal models, respectively. In this way, both methods will play important roles in the functional analysis of susceptibility genes.

As noted, one major advantage of animal models is the ability to study the role of a risk gene in the establishment of neural circuits underlying behavioral abnormalities. To accomplish this, various molecular techniques can be used to disrupt or "knockout" the function of a gene. Mouse knockout models have been instrumental in studying risk genes in multiple childhood neuropsychiatric disorders, including ASD, obsessive–compulsive disorder, and schizophrenia (106). These studies highlight the utility of using mouse knockout models to elucidate biologic mechanisms involving genes that confer risk for these disorders. For example, Fragile X syndrome (FXS) is the most common inherited cause of ID and is associated with an increased risk of ASD. Mice lacking the function of *FMR1,* the gene that causes FXS, exhibit hyperactivity and deficits in a novel spatial learning task (107) . *FMR1* knockout mice also display structural abnormalities in their dendritic spines, similar to findings in individuals with FXS (108). Additional studies revealed that loss of *FMR1* in the mouse hippocampus results in increased long-term depression, a form of synaptic plasticity dependent on metabotropic glutamate receptor signaling (109). Importantly, these studies using a mouse knockout model identified a novel biologic mechanism underlying FXS and a potential pharmacologic pathway for therapeutic interventions (109).
FIGURE 3.3.2.8. The cost of sequencing a human genome. The National Human Genome Research Institute (NHGRI) has tracked the costs associated with DNA sequencing performed at the sequencing centers funded by the Institute. This information has served as an important benchmark for assessing improvements in DNA sequencing technologies. To illustrate the nature of the reductions in DNA sequencing costs, the graph also shows hypothetical data reflecting Moore's Law, which describes a long-term trend in the computer hardware industry that involves the doubling of "compute power" every 2 years. Technology improvements that "keep up" with Moore's Law are widely regarded to be doing exceedingly well, making it useful for comparison. Note the logarithmic scale on the y-axis and the sudden and profound outpacing of Moore's Law beginning in January 2008; this is the time when sequencing centers transitioned from Sanger-based "next-generation" DNA sequencing technologies. (*Courtesy of the National Human Genome Research Institute*.)

Animal models also enable the investigation of risk gene function along a developmental trajectory, including embryonic stages (105). This is highly relevant for ASD, given that many recently identified ASD risk genes are expressed embryonically (98). Moreover, it is possible to generate animal models in which the function of a particular gene can be activated or silenced only under certain conditions, for example, in a specific cell type or at a defined developmental stage. These studies are instrumental in establishing when and where a gene is necessary for brain development. For example, mice lacking the function of *MeCP2,* which is disrupted in most cases of Rett syndrome, a neurodevelopmental disorder affecting motor coordination and language development, exhibit similar behaviors as affected humans, including the developmental onset of stereotypical forelimb movements (110). Interestingly, a recent study utilized a mouse model to demonstrate that the selective loss of *MeCP2* in inhibitory neurons leads to behavioral abnormalities, while the introduction of functional *MeCP2* in these cells is able to reverse some of these behavioral deficits (111). This study highlights the role of a risk gene in a specific neuronal population, providing insight into a biologic pathway underlying Rett syndrome.

Further, animal models can be used to assess the function of variants identified in human genetics studies. This is critically important, given that one of the current challenges in the genetics of neuropsychiatric disorders is distinguishing deleterious and neutral variation. That is, large-scale whole-exome and whole-genome sequencing projects have revealed considerable variation at the sequence and structural levels in the genomes of both affected and unaffected individuals,

complicating the assignment of risk to rare transmitted missense variants or common variants in a known risk gene (112). While in silico approaches are useful for predicting the effect of a mutation on protein function, animal models provide an in vivo system to assess this. For example, it is possible to introduce or "knock-in" a gene carrying a patient-specific mutation in an animal model to test the extent to which this version of the gene can reverse or "rescue" phenotypes in a knockout animal. In this way, these studies provide a biologic readout of the function of variants identified in risk genes.

In addition, there are various emerging molecular technologies that are expanding the range of information that can be obtained from animal models both at the neuroanatomical and circuit levels. For example, a recently developed method, called CLARITY, allows for imaging intact tissue from mouse brain at high resolution without the need for sectioning (113). The application of this technology to analyze brain tissue from animal models of neuropsychiatric disorders as well as human clinical specimens has the potential to reveal subtle structural differences and to provide insight into pathophysiology (113). Also, there have been recent advances in techniques for imaging cellular activity in an awake, behaving animal, such as optogenetics, in which specific cells are engineered to express a channel that can be activated in response to light during a behavioral task, or the use of genetically encoded calcium indicators, such as GCaMP, which generate a fluorescent signal when cells are active (114,115). These techniques are beginning to illuminate the neural circuitry underlying behavior (116–118). Further, the availability of improved molecular technologies, such as the CRISPR (clustered regularly interspaced short palindromic repeats)/Cas9 system (119), which induces mutations in a gene of interest with a high degree of efficiency and flexibility, is facilitating the generation of knockout or knock-in animal models. The ability to generate animal models efficiently is critical to keep pace with the rapidly expanding list of risk genes emerging from large-scale human genetics studies.

Another advantage of animal models is the ability to conduct pharmacologic screens to identify compounds that reverse phenotypes resulting from the disruption of a specific risk gene. Here, model systems such as *Drosophila* and zebrafish are emerging as practical alternatives to mice, given the ease of genetic manipulation and the ability to conduct high-throughput drug screens in these systems at a scale that is impractical in mice, given their larger size (104). While mice offer greater conservation to humans (mice and humans share 99% of their genes), these less complex model systems share a reasonable degree of conservation to humans at the genetic level, with *Drosophila* and zebrafish sharing 75% and over 80% of their genes with humans, respectively (104). There is also evidence for conservation of neurochemical pathways (104,120,121), such that studies using these systems are translatable to neuropsychiatric disorders. For example, disruption of the fly ortholog of the *FMR1* gene resulted in abnormal courtship behavior and neuroanatomical

changes that were reversed by treatment with metabotropic glutamatergic antagonists (121), similar to findings implicating this pathway in knockout mice. In addition, studies of zebrafish lacking the function of risk genes associated with ASD or epilepsy led to the identification of novel pharmacologic compounds with relevance to these disorders (122,123). While there is a "trade-off" between the range of studies that can be conducted in less complex systems and their similarity to humans (104), it is likely that an increasing number of functional analyses of risk genes will utilize multiple animal models to harness the distinct advantages of each system.

At the same time, there are limitations to the use of animal systems for modeling neuropsychiatric disorders. First, human-specific behaviors cannot be fully recapitulated in an animal system (104–106). Face validity, or the extent to which a quantifiable behavior in an animal model represents a related behavior in humans, may be limited (106). For example, in mouse models, the time an animal spends in an open field compared to the rim of an enclosure may be used as a measure of anxiety, and repetitive grooming is considered representative of obsessive–compulsive behavior (106). While these assays cannot encompass the range of clinical symptoms associated with neuropsychiatric disorders in humans, animal models can provide critical insights into the biologic processes underlying behavior at the molecular and circuit levels. Second, pharmacologic compounds identified in animal models may not translate to humans. For example, metabotropic glutamatergic receptor antagonists reverse physiologic and behavioral abnormalities in animal models of FXS, yet these compounds have yet to be successful in clinical trials (124). Their apparent lack of efficacy may be due in part to issues in clinical trial design, such that administering the medication to younger individuals for a longer period of time or developing more precise measures to assess efficacy may improve outcomes (124). Third, it may not be possible to recapitulate some genetic abnormalities using animal models due to limits of genetic conservation. For example, CNVs are more difficult to replicate in animals than single nucleotide mutations, and animal models cannot capture the genetic diversity present in a particular individual, which may influence clinical presentation. Nonetheless, animal models play an important role in advancing from risk gene identification to the discovery of biologic mechanisms with relevance to childhood neuropsychiatric disorders.

Animal models are a key component of translating human genetics findings "from bench to bedside." Given the growing list of risk genes in neuropsychiatric disorders resulting from large-scale sequencing efforts, there is an increased need to investigate the extent to which these genes converge on common neurodevelopmental pathways using in vivo systems. With the emergence of novel technologies to examine neuronal activity in an awake, behaving animal, animal models offer considerable promise to illuminate the effect of risk gene disruption on the establishment of neural circuits underlying behavioral deficits. At the same time, the relevance of an animal model for a human disorder often relies on the strength of the

evidence from human genetic studies implicating the risk gene under investigation. Therefore, continued progress in the ability to identify with confidence genes that are strongly associated with childhood neuropsychiatric disorders will be critical for elucidating the biologic mechanisms underlying these disorders and developing improved pharmacologic treatments.

Stem Cell Modeling

Another strategy for translating human genetic findings is the generation of iPSCs to model disease. In 2007, Yamanaka et al. reported in their landmark paper that adult human dermal fibroblasts could be reprogrammed into a pluripotent state using just four transcription factors, Oct3/4, Sox2, Klf4, and c-Myc (125). These iPSCs could, in turn, be differentiated into any cell type of the body, including neural cells. This development revolutionized the biologic investigation of neuropsychiatric disorders since the field is severely challenged by the unavailability of living brain tissue for cellular and molecular studies. Since then, numerous research groups have adopted this technique to reprogram a variety of mature cell types, including fibroblasts, lymphocytes (126), lymphoblastoid cell lines (127), dental pulp cells (128), and renal epithelial cells present in urine (129).

Although postmortem studies have been invaluable in revealing abnormalities of patient brain tissue, such as in cytoarchitecture (130) and gene expression (131) for disorders like ASD and schizophrenia, postmortem tissue also has limitations that can be overcome by iPSCs (130,132). Variability in parameters such as cause of death, time to collection, fixation methods, and storage conditions can confound results. Furthermore, it is difficult to determine if any findings are specific to the pathophysiology of the disorder as opposed to the lifetime accumulation of environmental effects, including treatments. The absence of living cells does not allow for functional studies, such as the electrophysiologic properties of neurons and neural circuits.

As discussed above, animal models have a long tradition of providing valuable insights into human disorders but also have limitations that can be complemented by iPSCs. Compared to iPSCs, animal breeding is more resource intensive in terms of time, space, and expense. The genome of animal models is often manipulated to recreate mutations identified in patients. Although it can be very informative to isolate the effects of a single mutation, the genetic background of the patient, which can have critical influence on disease expression, is missing (133). Also, multiple mutations within an individual and large CNVs make important contributions to the genetic architecture of complex neuropsychiatric disorders, but these are very difficult to model in animals (130). Species differences in genetics, neurobiology, and behavior mean that it is difficult to recapitulate the cognitive, affective, social, and behavioral phenotypes, which are often uniquely human. Still, no one model will

completely elucidate the pathophysiology of a disorder. The multimodal approach is most likely to reveal the fullest picture. In their review, Habela et al. (130) provide the example of FXS: while postmortem studies and mouse models show increased dendritic spine density, iPSC-derived neurons show fewer and shorter spines. Further investigation will be needed to resolve these contradictory results, which may be due to possibilities such as compensatory mechanisms in the patient condition or the influence of culture conditions on iPSC-derived neurons (130).

As with any modeling technique, there are important advantages and limitations to using iPSCs. Since they can be generated from mature cells, iPSCs avoid the ethical and policy complications of using embryonic stem cells (ESCs). Source cells can be obtained by relatively simple, noninvasive, and common procedures, such as skin biopsy, blood draw, saving teeth which have been naturally shed, and urine collection. Unlike primary cell cultures, which have limited proliferative capability, iPSCs propagate indefinitely. Through specific culture conditions, which require the addition and/or withdrawal of the appropriate growth factors, iPSCs can be differentiated into any cell type of the body. Protocols have been developed to direct differentiation into electrically active glutamatergic, GABAergic, dopaminergic, and motor neurons; astrocytes; and oligodendrocytes. However, protocols need to be established for other important cell populations in the brain, such as cortical layer-specific neurons, various GABAergic neuronal subtypes, Purkinje cells, microglia, and endothelial cells (134,135). Co-culturing neuronal and nonneuronal cells would be expected to better capture disease-relevant phenotypes. The ability to produce excitatory neurons, inhibitory interneurons, and astrocytes can be very useful to probe the excitatory/inhibitory imbalance that has been identified as a feature of neuropsychiatric disorders such as ASD and schizophrenia (134).

Two popular approaches to iPSC modeling involve: (1) generating iPSCs from patient cells and (2) generating iPSCs from a healthy individual, which are then engineered to carry a patient mutation. The obvious advantage of the first approach is that it preserves the genetic background of the patient. This is especially important in complex neuropsychiatric disorders, which may result from the interaction of multiple mutations within an individual. Furthermore, iPSCs can be generated from patients for whom a genetic etiology has not been established; abnormal cellular and molecular phenotypes can still provide clues as to disease mechanism, as has been shown for idiopathic ASD (136). In those with defined genetics, genome editing techniques, such as the CRISPR/Cas9 system mentioned above (137), can be used to correct the mutation(s) to determine whether it was necessary to cause any abnormal phenotypes. By the second approach, a panel of isogenic lines can be created, each of which is engineered to carry a different disease-associated mutation. This allows for isolating and comparing the effects of each mutation without the confound of differing genetic backgrounds, and tests whether a mutation is sufficient to cause abnormal phenotypes. Combined, these approaches provide two pairs of well-matched,

rigorously controlled cell lines, which can strengthen the evidence for association between any one mutation and disease (Figure 3.3.2.9), and is especially important in highly multigenic disorders.

Another advantage of iPSC modeling is that the differentiation of iPSCs to neural progenitor cells (NPCs) and mature neural cells enables the study of the full developmental process. Numerous features can be examined, including gene expression, cell proliferation, differentiation, organization, migration, morphology, synapse formation and function, etc. Neural cells can be grown in a two-dimensional monolayer culture, which facilitates cell-based assays. Neural cells can also be grown as three-dimensional organoids, which more closely, but by no means completely, recapitulate early human brain development. They may better capture cell–cell signaling and simplified network activity (134,138). iPSC modeling allows for the testing of environmental stressors on neural development and function. It is generally believed that both genetics and environmental factors contribute to many neuropsychiatric disorders; gene x environment interactions can be investigated in iPSCs and iPSC-derived neural cell lines. Through automation, iPSCs can offer a platform to screen the effects of hundreds of mutations and identify potential targets for treatment. Similarly, iPSCs can offer a high-throughput platform to screen for drugs that reverse abnormal phenotypes. The use of patient iPSCs also furthers the goal of personalized medicine.

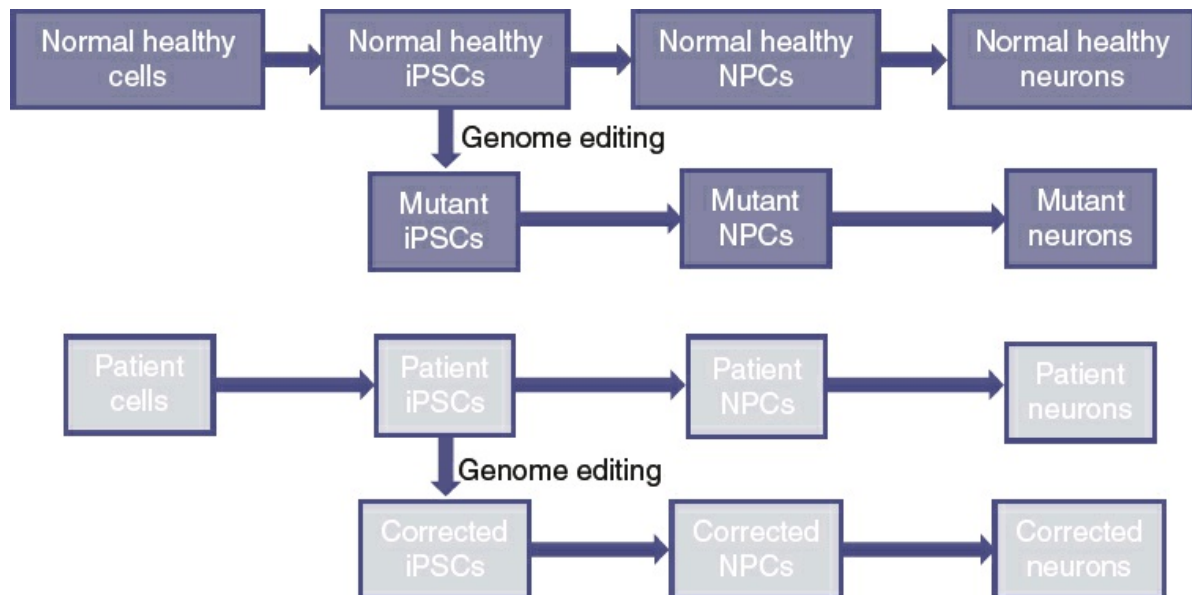
As no one technique is expected to perfectly model neuropsychiatric disorders, it is important to be aware of the limitations of iPSCs. Despite its many advantages, it is still an in vitro model of complex brain organization and function. The neural cell lines produced by current differentiation methods allow for the identification of cellular and molecular phenotypes but limit the interrogation of complex neural networks. The generation of iPSCs, NPCs, and neural cells are not quick protocols. It can take a month to reprogram source cells into iPSCs, a month to differentiate iPSCs into NPCs, and 3 to 4 months for NPCs to develop into neural cells. The generation of iPSCs is labor intensive, since iPSC clones are prone to spontaneous differentiation at their periphery and require frequent “cleaning.” Gene expression profiling studies have shown that the neurons tend to be immature (139), which could decrease their relevance to disease modeling. Therefore, it is important to determine the maturation status of iPSC-derived neurons. Some research groups are developing protocols to transform source cells directly into neural cells by forcing expression of lineage-specific transcription factors (133). This would greatly speed up these investigations. However, eliminating the normal developmental process may also eliminate important disease-related phenotypes, especially for neurodevelopmental disorders such as ASD.


FIGURE 3.3.2.9. Two popular approaches to induced pluripotent stem cell (iPSC) modeling. Two pairs of well-matched cell lines derived from (1) a normal healthy individual in whom a mutation has been introduced and (2) a patient in whom the mutation has been corrected by genome editing. Combined, these approaches provide two pairs of well-matched, rigorously controlled cell lines, which can strengthen the evidence for association between any one mutation and disease, and is especially important in highly multigenic disorders. NPCs, neural progenitor cells.

A major concern of iPSC modeling is genetic and epigenetic variability, which has been detected between iPSC lines, between iPSC and ESC lines, between different passages of the same iPSC line, and between different populations at the same passage number of the same iPSC line (140). Concerns have been raised that the reprogramming process may introduce mutations, although a study showed that genetic mosaicism of the source cells accounted for most of what appeared to be de novo CNVs (141). Given the variability, it is critical that multiple, independent iPSC lines are generated for each mutation or patient. It is also critical to study well-matched, rigorously controlled cell lines as described earlier. The magnitude of this problem was clearly demonstrated by a study of iPSC models of Parkinson disease (PD) (142). The researchers generated iPSCs from patients with the PD-associated LRRK2 G2019S mutation and unrelated healthy controls. They used genome editing to correct the G2019S mutation in patient iPSCs and introduce this mutation into control iPSCs. Transcriptome profiling and cluster analysis of the iPSC-derived neurons revealed that some patient and control lines clustered with each other rather than with their own groups as would be expected. Only the matched patient and patient-corrected lines consistently clustered closely together.

Reprogramming, by definition, involves genome-wide epigenetic changes, including changes in DNA methylation and histone modification (143). However,

there are reports of incomplete reprogramming and epigenetic alterations, including at imprinted loci and the inactivated X chromosome, during prolonged culturing (140). This raises concerns for modeling disorders of genomic imprinting and X-linked disorders. However, iPSCs generated from patients with Angelman and Prader–Willi syndromes were found to retain the appropriate DNA methylation patterns (144). In addition to studying multiple, independent, rigorously controlled cell lines, it may be advisable to assess epigenetic patterns before and after generation of iPSCs. Mutation correction experiments can also help determine if abnormal phenotypes are due to the specific mutation under study or confounded by genetic and/or epigenetic variability.

Several reviews have catalogued iPSC modeling of a variety of neuropsychiatric disorders, including genetic syndromes, ASD, schizophrenia, bipolar disorder, and depression (130,132–135,145). The growing number of studies are providing critical insights into pathophysiology, and identifying potential targets for treatment.

CONCLUSIONS

Rapidly advancing technologies in human genetics have provided significant insights into the etiology of childhood neuropsychiatric disorders, but they have only uncovered the tip of the iceberg regarding pathophysiology. Now that a growing list of genes are being strongly associated with these disorders, it is critical to determine precisely how mutations affect the structure and function of proteins and contribute to the development of disease. As discussed above, a multimodal approach, which includes the study of animal models, postmortem brain tissue, and cellular models, will yield the best information since each technique has strengths and weaknesses and, indeed, complement each other. They will help achieve the ultimate goals of elucidating pathophysiology, identifying targets for treatment, and screening therapeutic agents.

CHAPTER 3.3.3 ■ MOLECULAR BASIS OF SELECT CHILDHOOD PSYCHIATRIC DISORDERS

SIMONE TOMASI, JESSICA B. LENNINGTON, JAMES F. LECKMAN, AND PAUL J. LOMBROSO

The past several decades have seen remarkable progress in the application of molecular genetic strategies to the study of neurologic and neuropsychiatric disorders (1,2). The chromosomal location for many autosomal-dominant, autosomal-recessive, and X-linked disorders has been accomplished (Table 3.3.3.1). The genes mutated in a number of these illnesses have been identified and determining the function of both the normal and mutated proteins has begun. This chapter reviews some of the important accomplishments in this area. It begins with a discussion of the molecular basis of normal learning and memory and how mutations of key signaling proteins can lead to developmental disorders, and concludes with a brief consideration of the molecular basis of additional child psychiatric disorders.

LEARNING AND MEMORY

The ability to learn something new and then consolidate that information into long-term memories is part of normal development. As clinicians, we are often asked to evaluate whether a child is developing appropriately. Are specific skills emerging at the appropriate time points or are there delays? Landmarks include the ability to speak, to read, or to interact appropriately with peers. The mechanisms by which children learn to sit and crawl, walk and talk, and develop social skills have been the intensive focus of psychologists and psychiatrists over the years.

It is only in the past few decades that investigators have begun to study these questions at a molecular level (3,4). What has emerged is a fascinating story of how cells within the central nervous system (CNS) communicate with each other during learning and initiate a series of events that lead to the formation of long-lasting memories. Equally interesting is the finding that disruptions to these normal processes can contribute to developmental disorders. First we review some of the mechanisms by which normal learning develops before discussing disorders that occur when these processes are disrupted.

A central concept to emerge from research on learning and memory is that the formation of long-term memories requires both biochemical and structural modifications within neurons. The transformation of short-term, labile memories into more stable, long-term memories requires growth at specialized points of neuronal contact termed synapses. Synapses change shape as learning proceeds—new synapses are formed and old ones are strengthened. This phenomenon, termed synaptic strengthening, is found in all parts of the brain where memories are formed.

When an action potential arrives at the end of the axon, synaptic vesicles fuse with

the presynaptic terminal membrane and release one or more of a variety of neurotransmitters. The transmitters diffuse across the narrow synaptic cleft and bind to receptors on the postsynaptic terminal. Neurons communicate in this way, and the subsequent processing of the incoming signal at the postsynaptic terminal results in long-lasting changes in both the shape and biochemical composition of synapses.

A tremendous amount of research has been devoted to understanding this process over the last decade (5). To summarize, a signal arrives at the surface of a neuron and induces the production of proteins required for the morphologic and biochemical changes at the synapse. This experience-induced synaptic strengthening underlies memory formation, and the molecular mechanisms by which this occurs are reviewed next.

One of several key players in these events is a member of the mitogen-activated protein kinase (MAPK) family of proteins, the extracellular signal-regulated kinases 1/2 (ERK1/2) (6–8). The arrival of a signal at the postsynaptic terminal activates a cascade of signaling proteins that leads to the activation of ERK1/2 (Figure 3.3.3.1). The ERK pathway is activated in all brain regions where synaptic plasticity occurs and is necessary for the formation of new long-term memories (5).

ERK1/2 are members of a family of enzymes termed kinases that add phosphate groups to its target substrate proteins. The addition of bulky negatively charged phosphate groups often results in a change in the three-dimensional shape of the phosphorylated protein. As an example, the conformational change may expose a previously hidden amino acid domain buried deep within the structure of the protein. The exposure of the domain now permits interactions of the protein with other proteins further downstream in a cascade. Phosphorylation and activation of ERK1/2 leads to the phosphorylation of a set of target transcription factors and these now initiate gene transcription (9). In this way, a signal originating at the surface of a neuron is communicated to the interior of the cell, and a group of proteins are produced that are necessary for the modifications at that specific spine that accompany synaptic strengthening. As a consequence, the neuron becomes more sensitive to future synaptic input; it responds with higher excitatory potentials than before. Moreover, the increase in responsiveness may last for prolonged periods of time, months, years or longer. This phenomenon, termed long-term potentiation, is thought to underlie the molecular changes that occur during the formation of stable, long-term memories (5,10).

As mentioned, ERK1/2 belong to the family of MAPK, which also includes c-Jun N-terminal kinase (JNK) and p38. JNK activation has been implicated in stress-induced associative learning in the hippocampus (11), whereas signaling through ERK1/2 is critical for long-, but not short-term memory (12–14). This role for ERK1/2 has been demonstrated by blocking the activity of ERK1/2 by injecting inhibitors of the activator of this enzyme into specific brain regions, such as the amygdala. As a consequence, the formation of memories that are normally

consolidated within that structure does not occur (e.g., fear conditioning) (15,16). Similarly, if ERK1/2 activity is blocked within the hippocampus, formation of memories that require the hippocampus is prevented (e.g., visual–spatial learning) (17). In a different set of experiments, ERK1/2 signaling was shown to be a critically involved in the control of reward-seeking behavior in the nucleus accumbens (18), a region of the basal brain which receives broad glutamatergic (from prefrontal cortex, hippocampal subiculum, thalamus, and amygdala) and dopaminergic (from ventral tegmental areas) inputs and plays an important role in reward and learning, as well as in addiction. Disruption of ERK1/2 activation resulted in a decrease in reward-seeking behavior (19).

TABLE 3.3.3.1

CHROMOSOMAL LOCALIZATION AND GENE ABNORMALITIES IN SELECTED PSYCHIATRIC AND NEUROLOGIC DISORDERS

Genetic Disorder	Chromosomal Location	Genetic Mutation (Protein)
Autosomal Dominant		
Amyotrophic lateral sclerosis	21q22.1	Point mutations (superoxide dismutase)
Benign familial neonatal convulsions 1	20q13.2	Point mutations (voltage-gated potassium channel)
Benign familial neonatal convulsions 2	8q24	Point mutations (a second voltage-gated potassium channel)
Charcot–Marie–Tooth disease		
Type 1A	17p11.2	Gene duplication, deletions, point mutations (peripheral myelin protein-22, PMP22)
Type 1B	1q23.3	Point mutations (myelin protein zero protein)
Alzheimer disease		
AD1	21q21	Point mutations (amyloid precursor protein)
AD2	19q13.2	Increased frequency of apoE4 allele
AD3	14q24.3	Point mutations (presenilin-1)
AD4	1q31-q42	Point mutations (presenilin-2)
Huntington disease	4p16.3	Triplet repeat (huntingtin)
Myotonic dystrophy	19q13.2	Triplet repeat (myotonin protein kinase)
Neurofibromatosis Von Recklinghausen	17q11.2	Deletions, insertions, translocations, and point mutations (neurofibromin)
Acoustic neuroma	22q.12.2	Translocations, deletions, point mutations (merlin)
Parkinson disease	4q21	Point mutations (α-synuclein)
Spinocerebral ataxia	6p23	Triplet repeat (SCA1)
Imprinting Disorders		
Angelman syndrome	15q11-12	Deletion, uniparental disomy, point mutations, imprinting center mutation (UBE3A)
Prader–Willi syndrome	15q11-12	Deletion, uniparental disomy, imprinting center mutation (candidate protein: SNRNP)

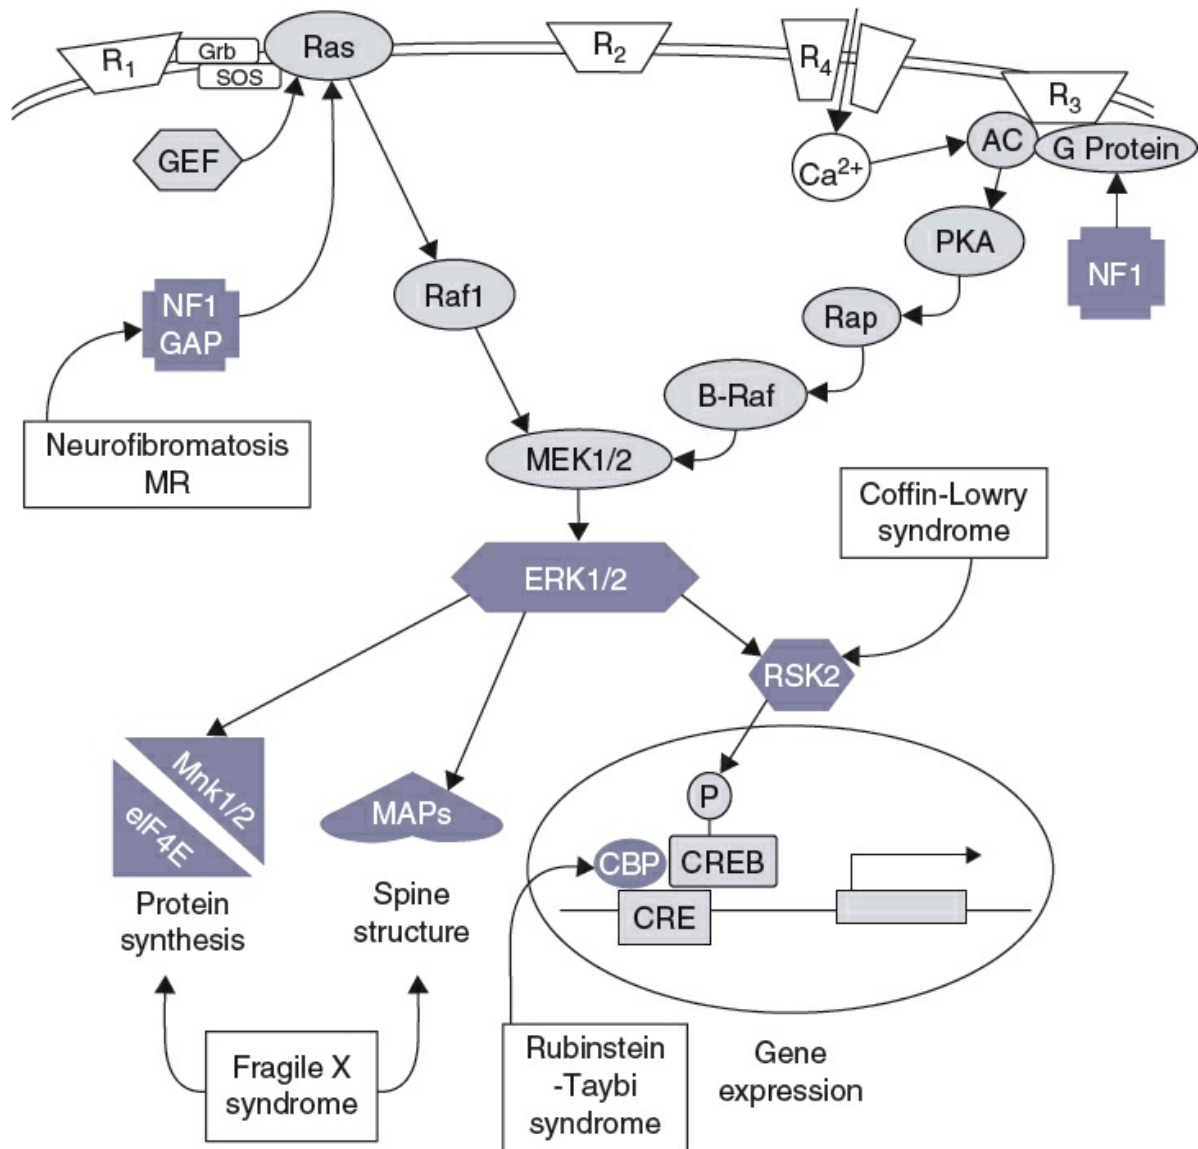
Autosomal Recessive		
Ataxia telangiectasia	11q23	Translocation, deletions, point mutations (ATM)
Gaucher disease	1q21	Point mutations (glucocerebrosidase)
Lissencephaly Miller–Dieker	17q13.3	Deletions (lissencephaly 1)
Milder lissencephaly	17q13.3	Point mutations (lissencephaly 1)
Phenylketonuria	12q24	Deletions, point mutations (phenylalanine hydroxylase)
Parkinson disease	6q25.2-q27	Point mutations, deletions (parkin)
Retinoblastoma	13q14	Deletions, point mutation (retinoblastoma)
Rubinstein–Taybi syndrome	16p13.3	Translocation, deletions, point mutations (CREB-binding protein)
Schizencephaly	3q25-q26	Candidate gene (homeobox gene emx2)
Waardenburg syndrome	2q35	Deletions, point mutation (Pax-3)
Williams syndrome	7q11.23	Deletions (multiple candidate genes)
Wilson disease	13q14.21	Point mutations, deletions (copper-transporting ATPase)
Velocardiofacial syndrome	22q11	Candidate gene (UFDIL)
X-Linked Recessive		
Muscular dystrophy		
Duchenne dystrophy	Xp21.21	Large deletion (dystrophin)
Becker dystrophy	Xp21.21	Small deletion (dystrophin)
Fragile X syndrome	Xq27.3	Triplet repeat (FMR-1)
Lesch–Nyhan syndrome	Xq27	Deletions, point mutations (HGPRT)
Lissencephaly (double-cortex)	Xq22.3	Translocation, point mutations (doublecortin)
Rett syndrome	Xq28	Point mutations (MeCP2)
Spinobulbar muscular atrophy	Xp21.3	Triplet repeat (androgen receptor)
Mitochondrial Diseases with Maternal Transmission		
Leber hereditary optic atrophy	Mitochondria	Point mutations (NADH dehydrogenase)
Mitochondrial myopathy	Mitochondria	Deletion (candidate genes: Cox II and cytochrome b)


FIGURE 3.3.3.1. The ERK MAPK cascade is affected in human mental retardation syndromes. The mitogen-activated protein kinase (MAPK) family includes two important members that are involved in many different forms of learning and memory. These proteins are termed extracellular signal-regulated kinases (ERKs) to reflect the fact that they were initially characterized as kinases that became activated after growth factors bound to specific receptors at the outer surface of a cell's membrane. Upstream regulators and selected potential downstream targets of the ERK MAP kinase cascade are shown, along with known sites of derangement in human mental retardation syndromes. One current model is that MAPK plays multiple roles in memory formation: Modulating the induction of lasting synaptic changes through regulating voltage-dependent potassium channels and triggering long-lasting changes through regulating gene expression via CREB phosphorylation. Other possible sites of action are regulating local protein synthesis, regulating cytoskeletal proteins, and regulating other ion channels

such as the AMPA subtype of glutamate receptor. (Adapted with permission from Sweatt JD, Weeber EJ, Lombroso PJ: Cognitive disorders and the ras/ERK/CREB pathway. *J Am Acad Child Adol Psychiatry* 42:741–744, 2003.)

A key point in the present discussion is that a series of proteins are "upstream" of ERK1/2 and therefore necessary for its activation, while other proteins are "downstream" of activated ERK1/2 and are required for transcriptional activation. ERK1/2 signaling is activated by both glutamate (20) and dopamine signaling (21), as well as by neurotrophins such as brain-derived neurotrophic factor (BDNF) (22). Several targets have been characterized downstream of ERK1/2; among these, cyclic AMP response element binding protein (CREB) and Elk1 are two well-characterized transcription factors involved in long-term synaptic plasticity and memory in the hippocampus and other brain regions (23,24). It follows that disruption of components of this multistep pathway might disrupt the development of synaptic strengthening and contribute to developmental delays. Mutations have recently been discovered in several genes involved in this pathway and these mutations lead to the three developmental disorders that are discussed next.

Neurofibromatosis. Neurofibromatosis is an autosomal-dominant disease with clinical features that include neural-derived tumors and café-au-lait spots throughout the body. Approximately half of the affected individuals are also intellectually disabled (25). The gene that causes neurofibromatosis type I (*NF1*) was recently characterized and several mutations were identified in affected patients (26). Variability in the types of mutations (point mutations, insertions, or deletions) reflects a high level of phenotypic heterogeneity. It has been recently proposed that nongenetic, stochastic factors may contribute to the severity of symptoms, as suggested by the occurrence of loss of heterozygosity at *NF1* and "second-hit" mutations in neurofibromas, astrocytomas, malignant peripheral nerve sheath tumors, and pheochromocytomas from patients with *NF1* mutations (27).

The region of the gene that is mutated determines whether or not the child develops cognitive deficits, in addition to the characteristic benign tumors. In other words, the normal neurofibromin protein has several amino acid domains with distinct cellular functions. One of the domains regulates cellular proliferation, and mutations within this region of the gene lead to the unregulated proliferation of cells and the formation of tumors. Another portion of the protein regulates the ERK1/2 pathway, and mutations within this region interfere with the ability of neurofibromin to downregulate the ERK1/2 pathway. At least 200 mutations of another gene, *NF2*, have been reported for neurofibromatosis type II. *NF2* encodes a tumor-suppressor protein, merlin, which normally suppresses the Ras-ERK1/2 signaling pathway (28). As a consequence, the ERK1/2 pathway is overactive and does not respond appropriately to incoming neuronal signals. Normal synaptic strengthening does not

occur and individuals with this type of mutation have cognitive disabilities (29).

Coffin–Lowry syndrome. A mutation in another protein in the classical ERK1/2 pathway leads to Coffin–Lowry syndrome, which is inherited in an X-linked manner (30). Several pathogenic allelic variants have been described throughout the *RSK2* gene, although their correlation with a specific phenotype has not been identified. Most variants are associated with protein truncation due to missense or nonsense mutations; intragenic deletions were observed in 21% of cases, as well as partial or full gene duplications. Interestingly, benign allelic variants have also been described, which are not associated with Coffin–Lowry syndrome (31,32). One of the downstream targets of the ERK1/2 pathway is a kinase called ribosomal S6 kinase (RSK2). RSK2 is a protein kinase that rapidly enters the nucleus upon activation and phosphorylates the transcription factor, CREB. The transcription factor CREB targets specific genes and induces their expression; in the absence of phosphorylation by RSK2, CREB remains less active. Mutations in the *RSK2* gene thus disrupt the normal cascade from the neuronal surface to the nucleus, interfere with gene transcription and the synthesis of proteins required for synaptic modifications (33). During neurite formation, nerve growth factor activates RSK2 that results in synthesis of phosphatidic acids and contributes to vesicle fusion at sites of synaptic growth (34). RSK2 has also been implicated in DNA repair and the control of genome stability (35).

Rubinstein–Taybi syndrome. A third disorder associated with mutations in the ERK1/2 pathway is Rubinstein–Taybi syndrome (RTS) (36). RTS individuals have characteristic clinical signs that include facial abnormalities, broad digits, and cognitive deficits. Recently, a mutation to the CREB-binding protein gene (*CBP*) was discovered in approximately 50% to 60% of patients with the RTS phenotype. The CBP protein is required for the normal unwinding of DNA that precedes the binding of transcription factors to promoter regions. As a result of the mutation, the transcription factor CREB cannot bind properly to the targeted DNA sequences that promote the initiation of gene transcription. Once again, synaptic strengthening is disrupted and normal learning does not develop. Pathogenic variants at the *EP300* locus have been recently described in 3% to 5% of patients with a milder cognitive impairment (37). EP300 is a histone acetyltransferase that acts as a transcriptional coactivator and tumor-suppressor protein; CBP and EP300 display high primary protein sequence similarities, but are implicated in distinct cellular functions, although the molecular alterations caused by *EP300* mutations have not been characterized yet.

FRAGILE X SYNDROME

The molecular biology of fragile X syndrome has advanced dramatically over the past few decades (38). This disorder is the second most common cause of cognitive

deficits after Down syndrome and the most common form of inherited intellectual disability. Initial estimates of the prevalence of disorder were based on the detection of the Xq27.3 fragile site and reported that as many as 1 in every 1,000 to 2,600 males were affected. However, recent molecular diagnostic tests assessing the *FMR-1* gene revised the prevalence to approximately 1 in 5,000 males (39) with prevalence in females approximately one-half of this estimate.

Children with fragile X syndrome are born with mild to severe cognitive deficits and approximately 50% of them meet the diagnostic criteria for autism (40). Additional clinical symptoms include facial, testicular, and connective tissue abnormalities (41,42). Abnormal speech patterns are present in the majority of cases and include echolalia and high-pitched speech, as well as poor articulation, dysfluency, and dyspraxia. Social anxiety and gaze aversion are common among these children, as well as stereotypic behaviors, hyperactivity, and attentional difficulties. Attention-deficit hyperactivity disorder (ADHD) is often diagnosed, with a peak in disruptive behavior during preschool years and a progressive decline with age, although attentional difficulties may persist (43). Aggressive and self-injurious behaviors are prominent features in some cases (44). Although there has been some interest in identifying specific linguistic, cognitive, or behavioral deficits among affected individuals, these have not been found (45–48). This is of some interest given the recent molecular discoveries discussed below indicating a general disruption to synaptic plasticity throughout the brain.

Fragile X syndrome is transmitted from one generation to the next as an X-linked disorder. It has been known for many years that the phenotype of fragile X syndrome often cosegregates with what appears to be a “fragile” site on the X chromosome. In a certain proportion of cells grown in the absence of the nutrient, folic acid, an apparent breakpoint becomes visible on one of the X chromosomes (Figure 3.3.3.2) (49). The chromosomal region is not in fact separated but rather does not stain normally on karyotype analyses. These findings suggested that the gene or gene(s) involved in the disorder might lie near the disrupted site.

FIGURE 3.3.3.2. Fragile X site. The fragile site is shown on an affected chromosome of an individual with fragile X syndrome. (Adapted with permission from Lubs H: A marker X chromosome. *Am J Hum* Gen 21:231–244, 1969.)

Several unusual aspects of the disorder were noted before the gene was actually cloned. Approximately 20% of the males who carry the abnormal gene are not cognitively impaired. If the gene lies on the X chromosome, why were these individuals not affected, as they have no normal copy of the gene to compensate for

the mutated gene? These individuals are called “normal transmitting males,” and pass the abnormal gene to their daughters, who may also be unaffected; however, their grandsons are at high risk for the full syndrome.

Several neurocognitive disorders show a progressive increase in severity over several generations, a genetic phenomenon known as anticipation. The molecular basis for anticipation is now understood, and relates to the molecular defect found in the affected *FMR-1* gene (50). A novel type of mutation was identified, termed a triplet repeat expansion. Triplet repeats refer to any three bases in the nucleotide sequence that are repeated as a unit several times. In the case of fragile X syndrome, the three repeated nucleotides are cytosine-guanine-guanine (CGG) in the 5’ untranslated region of exon 1, associated with hypermethylation, gene inactivation, and absence of the FMR protein (FMRP). Normal individuals have between 6 and 50 repeats of these bases at a specific site in their *FMR-1* gene, with 29 to 31 repeats being the most frequent (50). Affected individuals, however, have a dramatic increase in the number of repeated sequences, typically 200 to 1,000 repeats (*full mutation*). Mothers of affected probands often have numbers of CGG repeats that fall in between those seen in normal individuals and those affected with the full fragile X syndrome. Carriers thus typically have between 50 and 200 CGG repeats (50), and repeats in this range are called premutations. Expansion to a full mutation was observed in over 90% of mothers carrying 100 or more repeats (51). Mosaicism, the occurrence of two or more cell lines within the same individual with different genetic profiles, has been described in 15% to 20% of individuals with *FMR-1* mutations. This condition is associated with nearly 100% occurrence of intellectual disabilities in males, whereas a highly variable range was reported in females, from normal intellect to various degrees of cognitive impairment.

Individuals who carry the premutation of the FMR-1 gene may have mild cognitive and behavioral symptoms (52), including learning difficulties and social anxiety. Heterozygotic fragile X females perform poorly on visuospatial and/or memory subtests (53,54). Moreover, magnetic resonance imaging (MRI) and positron emission tomography (PET) analysis show that premutation female carriers have significant decreases in total brain volumes, as well as metabolic increases in the hippocampus and cerebellum (55).

Two phenotypes have been described more recently in premutation carriers. Premature ovarian failure is reported to affect 15% to 25% of female carriers (56). One-third of male premutation carriers over the age of 50 develop fragile X-associated tremor and ataxia syndrome (57,58). The molecular biology of these two distinct disorders remains unclear and does not appear directly related either to the CGG triplet repeat size or to the extent of FMRP deficit. Interestingly, a study from 2001 reported a paradoxical decrease in FMRP in permutation carriers with high levels of expression of the *FMR-1* gene (59). To explain this inconsistency, it has been hypothesized that overproduction of *FMR-1* mRNA might affect cytoplasmic

translocation of other mRNAs. In this view, premature ovarian failure and fragile X-associated tremor and ataxia is interpreted as a result of RNA-mediated toxicity (60).

In addition to the 200 to 1,000 CGG repeats in affected individuals, other DNA abnormalities are present. CpG islands were discussed in the previous chapter, and are regions often found within promoter regions with high content of the two bases, cytosine and guanine. Cytosines may be chemically modified by the addition of a methyl group, and large regions of methylated nucleotides regulate whether a gene is expressed or not. The relatively small triplet repeat found in unaffected individuals is present immediately downstream of the promoter region, in a region of the message that does not encode protein (61).

The triplet repeat expansion in fragile X produces a large increase in the number of methylated CpG islands (62), and methylated cytosines lead to a very tight DNA winding. Transcription factors that must gain access to the DNA to form transcriptional complexes are unable to bind and the normal transcription of the *FMR-1* gene is disrupted. The extent of methylation over the region correlates directly with the loss of functional protein (63). The methylated region also explains the observed "fragile site," as this region of DNA is tightly wound and does not stain well on karyotype analyses and therefore appears as a broken chromosomal region. To summarize, the abnormal methylation pattern is adjacent to the promoter region, interferes with normal transcription of the gene, and ultimately leads to the absence of functional protein in most affected individuals.

In individuals with normal allelic variants, it has been proposed that the presence of an AGG repeat between the CGG repeats could represent a protective mechanism against triplet repeat expansion, as it would anchor DNA and prevent the formation of secondary structures during DNA duplication. Indeed, the presence of long, uninterrupted CGG repeats seems to confer an increased risk for expansion (51,64,65).

What is the normal function of FMRP and how does its absence lead to clinical symptoms? Soon after the gene was isolated in 1991, researchers noticed that the protein contained three domains with highly conserved amino acid patterns. These domains are homologous to a motif found in proteins that bind to ribonucleic acid (RNA) molecules. These proteins are called RNA-binding proteins and are involved at multiple steps during the processing, trafficking, or translating of mRNA transcripts within cells (66–68). Indeed, FMRP contains both nuclear localization and nuclear export signals; this, along with the RNA-binding capacity, suggested that FMRP was regulating RNA subcellular localization by acting as a nucleocytoplasmic shuttling protein (69,70). A mutation in an RNA-binding protein might impair the ability of cells to produce mature messages or translate those messages into protein.

This disruption was in fact described in a fragile X patient who did not have the expected triplet repeat expansion, but instead had a point mutation that changed a single highly conserved amino acid normally present within one of the RNA-binding

motifs (68,71,72). The domain thus appeared to be critical for the proper function of FMR-1 protein, and mutations in this domain interfere with its ability to bind RNA molecules. In addition, this case indicated that although the majority of fragile X cases are caused by a triplet repeat expansion, any mutation that disrupts the functional activity of the FMR-1 protein could reasonably lead to a similar clinical syndrome. It is a good example of allelic heterogeneity, where mutations in different parts of a single gene lead to similar phenotypes.

Studies of the expression pattern of the *FMR-1* gene have identified areas of the brain that normally have high level of expression during development, including the basal forebrain and hippocampus (73). Both are involved in sequential processing of information and memory formation, and are affected in neurodegenerative disorders, such as Alzheimer disease. In addition, clinical neuroimaging studies have detected age-related volumetric changes in fragile X individuals in the cerebellar vermis, fourth ventricle, and hippocampus (74–76). Finally, the production of animal models, such as knockout mice, has been helpful in studying the underlying processes that are disrupted, as many of the clinical features seen in fragile X syndrome are present in these knockout mice (77).

A major advance in our understanding of the normal function of FMRP has come from two lines of investigation. The first has to do with the question of where proteins are translated within neurons. The older dogma was that messages produced within the nucleus were rapidly transported into the cytoplasm where they attached to ribosomes and deposit the translated proteins into the endoplasmic reticulum for further processing. This is the case for the majority of messages. However, within neurons, studies have now shown that a population of messages is actually transported throughout the dendrites and adjacent to the spines where synaptic contact is made. They remain there until an incoming signal arrives and initiates local protein synthesis at the very spines where the proteins are needed.

This new model has been helpful in solving a major difficulty with the earlier dogma. A typical neuron has up to 10,000 spines. Incoming synaptic activity arrives at perhaps a hundred of these spines. The previous model would have had the incoming signal activate a protein that would need to travel to the nucleus, initiate gene transcription and protein translation in the perinuclear region. The problem that arose was how proteins were then transported back to the hundred or so spines where the original signal arrived and where synaptic modifications were required.

The new model posits that the mRNA messages themselves are transported throughout the dendrites and deposited near spines, ready for an incoming signal to initiate translation. Evidence for this model has been extensive over the past several years, as various components of the translational machinery have been detected throughout dendrites and within the spines (77). These include the mRNAs themselves as well as ribosomes and a number of other proteins required for local protein synthesis (78).

It should be added that local protein synthesis does not preclude a signal from being sent from the activated spines back to the nucleus to initiate gene transcription. In fact, these signals must occur for long-term potentiation to be maintained and as long-term memories are consolidated. Thus, there is an initial burst of local protein synthesis that induces long-term potentiation, and a later phase during when mRNA messages are transcribed in the nucleus to maintain long-term potentiation. An interesting consequence of this process can be demonstrated by injecting transcriptional inhibitors into specific brain regions. If these inhibitors are injected into the amygdala, for example, short-term fear conditioning memories are formed, but this learning is not consolidated into long-term memories, as the maintenance of LTP requires protein synthesis.

Knowledge of the intracellular location of the FMRP protein has extended our understanding of its function. FMRP binds to ribosomes, the organelles within cells that are made from ribosomal RNA and various RNA-binding proteins, to function as factories that translate mRNA transcripts into proteins (79). FMRP has been shown to interact with several other molecules to inhibit translation of mRNA into proteins. FMRP is detected in several cellular structures, including P bodies (complexes of enzymes involved in mRNA decapping, storing and/or degradation of mRNAs), stress granules, and messenger ribonucleoproteins (mRNPs), consistent with its role in controlling translational events. In particular, FMRP is known to form homodimers and interact with a number of nuclear and cytosolic proteins, including the protein argonaute, microspherule protein, nuclear fragile X intellectual disability interacting protein, nuclear RNA export factor, dicer, and two FMRP paralogs (80).

FMRP binding to additional proteins leads to the repression of mRNA translation (81). Thus the loss of FMRP should cause an increase in protein synthesis. Control of mRNA translation by FMRP seems to be particularly important at synapses, as several crucial components of synaptic machinery are known targets of FMRP (82–85). A role in modulating mRNA stability has also been proposed for FMRP, which could either sustain or prevent mRNA decay (86). This work supports the notion that the loss of FMRP may have profound consequences on the molecular machinery controlling neuronal function.

Having solved one problem, researchers were left with another. Obviously, the messages that are transported down the neurites must not be translated until the proper synaptic input arrives. Recent work from several laboratories has suggested that inhibited translation is an important function of FMRP (38). FMRP attaches to newly synthesized mRNAs in the nucleus, accompanies these messages along the neuronal network, while inhibiting translation of the messages into proteins. When a signal arrives that normally would induce synaptic strengthening, the inhibitory actions of FMRP cease and the message is translated into proteins.

Exactly how this happens is not yet understood (85). One possibility is that the kinase ERK1/2 is involved. It is known that besides its ability to transduce signals

into the nucleus as described above, another function of activated ERK1/2 is to participate in the regulation of local protein synthesis at the spine itself (87,88). Presumably, these functions of ERK1/2 work in parallel: one to initiate rapid local protein synthesis and the second to translocate into the nucleus and activate gene transcription.

Several lines of evidence suggest that mRNA translation can be fine-tuned by posttranslational modifications of FMRP. Phosphorylation of FMRP on serine 499 residue was suggested to result in its association with stalled polyribosomes and translational repression, an event mediated by mTOR-dependent activation of S6K1 (89,90). However, mTOR-independent phosphorylation of FMRP has also been proposed (91). Because nonphosphorylated FMRP is associated with actively translating polyribosomes, it is also possible that releasing the inhibited translation induced by FMRP may depend upon a yet to be described mechanism (82,92).

The messages that are transported to the spines are a subset of messages found in neurons: messages that encode proteins necessary for the biochemical and structural modifications occurring at the synapse (93,94). FMRP is probably only one of a number of proteins required for this process. Many proteins are needed to support the transport of messages, their inhibition, and providing the scaffolding for local protein translation. It is possible that mutations that affect the function of these proteins may also disrupt synaptic strengthening to varying degrees and produce cognitive deficits in affected individuals.

The model presented in the previous paragraphs leads to certain predictions. If FMRP is necessary for synaptic strengthening, then the absence of this key player might result in detectable disruptions in spine morphology. William Greenough et al. showed that this was the case by using anatomical techniques to examine spines from patients with fragile X syndrome as well as a mouse model of the syndrome (95,96). Compared to the controls, they found larger numbers of long, spindly, and immature-looking spines in the fragile X cases, and fewer numbers of short, mushroom-shaped, and mature-looking spines. Taken together, these studies suggest that FMRP is involved in spine development by regulating the shape, number, and maturity of spines, which depends on the ability of FMRP to regulate local protein synthesis.

Expansion of the *FMR-1* gene by triplet repeats was originally thought to be a genetic anomaly unique to fragile X syndrome. However, more than a dozen other triplet repeat disorders have now been identified (Figure 3.3.3.3) including Huntington chorea, Friedreich ataxia, and myotonic dystrophy (97–101). The phenomenon of anticipation was apparent in most of these disorders but early investigators dismissed it as the result of ascertainment bias: affected individuals were more likely to bring in their children as symptoms emerged. The discovery of triplet repeat expansions, however, provided a molecular explanation. The degree of anticipation can be quite remarkable (Figure 3.3.3.4). In myotonic dystrophy, for example, expansions that are just above the threshold for disease may result in

cataract development late in life. Several generations later, descendants have the full expansion with long repeats and fatal congenital illness (102). Anticipation has also been described in families with schizophrenia and bipolar disorder, and some investigators believe triplet repeat expansions may account for a subset of these affected patients (103–109).

GENOMIC IMPRINTING: PRADER–WILLI AND ANGELMAN SYNDROMES

Half of our 46 chromosomes derive from our mothers and the other half from our fathers. For years, it had been assumed that genes that lay on either chromosomal pair were equivalent and that each produced the same amount of functional protein. Mutations present in one gene could often be overcome through the actions of the normal protein derived from the homologous gene.

This is an accurate description of the molecular events for the majority of genes; however, recent studies over the past decade have demonstrated that some gene pairs are not functionally equivalent. Instead, only one of the two genes is active and the other is repressed. The production of functional proteins depends on whether it is encoded by a gene on the chromosome derived from the mother or the one from the father. In some cases, the maternal gene is the gene expressed; in others cases, it is the paternal gene. This phenomenon is termed genomic imprinting.
FIGURE 3.3.3.3. Triplet repeat disorders. A hypothetical gene is shown prior to the splicing together of exons and the removal of introns to produce a mature RNA message. Triplet repeat expansions have been discovered in all regions of a gene. In fragile X syndrome, the cytosine-guanine-guanine (CGG) repeat lies in the 5′ untranslated region immediately adjacent to the promoter region. The expansion to 1,000 to 2,000 repeats leads to abnormal methylation patterns and disrupts normal transcription of the gene. In myotonic dystrophy, the cytosine-adenine-guanine (CAG) repeat is found at the other end of the gene within the 3′ untranslated region. It is believed that the expansion there results in an unstable mRNA prone to degradation, as well as perhaps affecting the transcription of a second nearby homeobox gene. In Huntington chorea, the triplet repeat expansion occurs in the open reading

frame of the gene and leads to the inappropriate incorporation of an amino acid, in this case glutamine, within the protein sequence. Triplet repeat expansions have also been found in introns, where they presumably interfere with the proper splicing of the message. Friedreich ataxia is an example of this type of expansion.

For the majority of disorders, mutations change the specific nucleotide sequence of a gene and thereby change the amino acid sequence of the encoded protein, but for a smaller group of disorders, factors other than the underlying nucleotide sequence determine whether the DNA produces useful patterns of gene expression. These epigenetic phenomena are fundamentally different from events that have an effect on the actual nucleotide sequences. We have discussed some epigenetic factors earlier in our discussion of methylation in fragile X syndrome and will do so again when we discuss Rett syndrome. In these disorders, chromatin and DNA packaging influences gene expression rather mutated nucleotide sequences.

Approximately 100 genes have been discovered so far that are imprinted, mostly, although not exclusively, in the brain (110). Many of them influence the growth and differentiation of various tissues, and their disruption is implicated in several cancers and developmental disorders. These advances are reviewed in the following section with an emphasis on two developmental disorders caused by imprinting defects, Prader–Willi and Angelman syndromes.

Prader–Willi syndrome. Prader–Willi syndrome (PWS) is a rare disorder with a prevalence of 1 in 10,000 to 1 in 30,000 births that results in a constellation of symptoms arising shortly after birth (111). Infants are often hypotonic and fail to thrive; however, their dietary habits change within the first year or two of life, and these individuals typically become hyperphagic and obese (112). They often have mild to moderate cognitive disabilities and a number of additional behavioral problems that include temper tantrums, aggressive behaviors, and obsessive–compulsive symptoms outside of the compulsive food-related behaviors (45,113,114).

Angelman syndrome is also a relatively rare disorder with a prevalence of 1 in 12,000 to 24,000 births. Individuals with the disorder are also hypotonic as infants and develop motor delays and moderate to severe cognitive disabilities. They have a characteristic face with a large mandible with an open-mouth expression, disproportionate head circumference, abnormal gait, and puppet-like limb movements; they rarely develop speech. Affected individuals often have an abnormal electroencephalogram and develop epilepsy early in life (115).

By the mid-1980s, it was known that both disorders are caused by a deletion on chromosome 15 (15q11.2–q13) (Figure 3.3.3.5). Cytogenetic and molecular techniques showed that the same region of chromosome 15 is deleted in individuals with either syndrome. The disorders are very different, yet the identical deletion

seemed to cause PWS in some cases and Angelman syndrome in others (116,117). It was then discovered that the clinical symptoms depend on which parent donates the deleted chromosome (118). The deletion derives from the father in most cases of PWS, and most individuals with Angelman syndrome have the same deletion but it is on the chromosome derived from the mother.

A further clarification of the underlying mechanism came when the region for each disorder was pinpointed to a small region on chromosome 15. The section of DNA responsible for PWS is distinct but very close to the area responsible for Angelman syndrome. Part of the puzzle was thus clarified. A large deletion often spans both regions. The child develops PWS if the deletion occurs on the paternal chromosome and Angelman syndrome if the deletion occurs on the maternal copy.

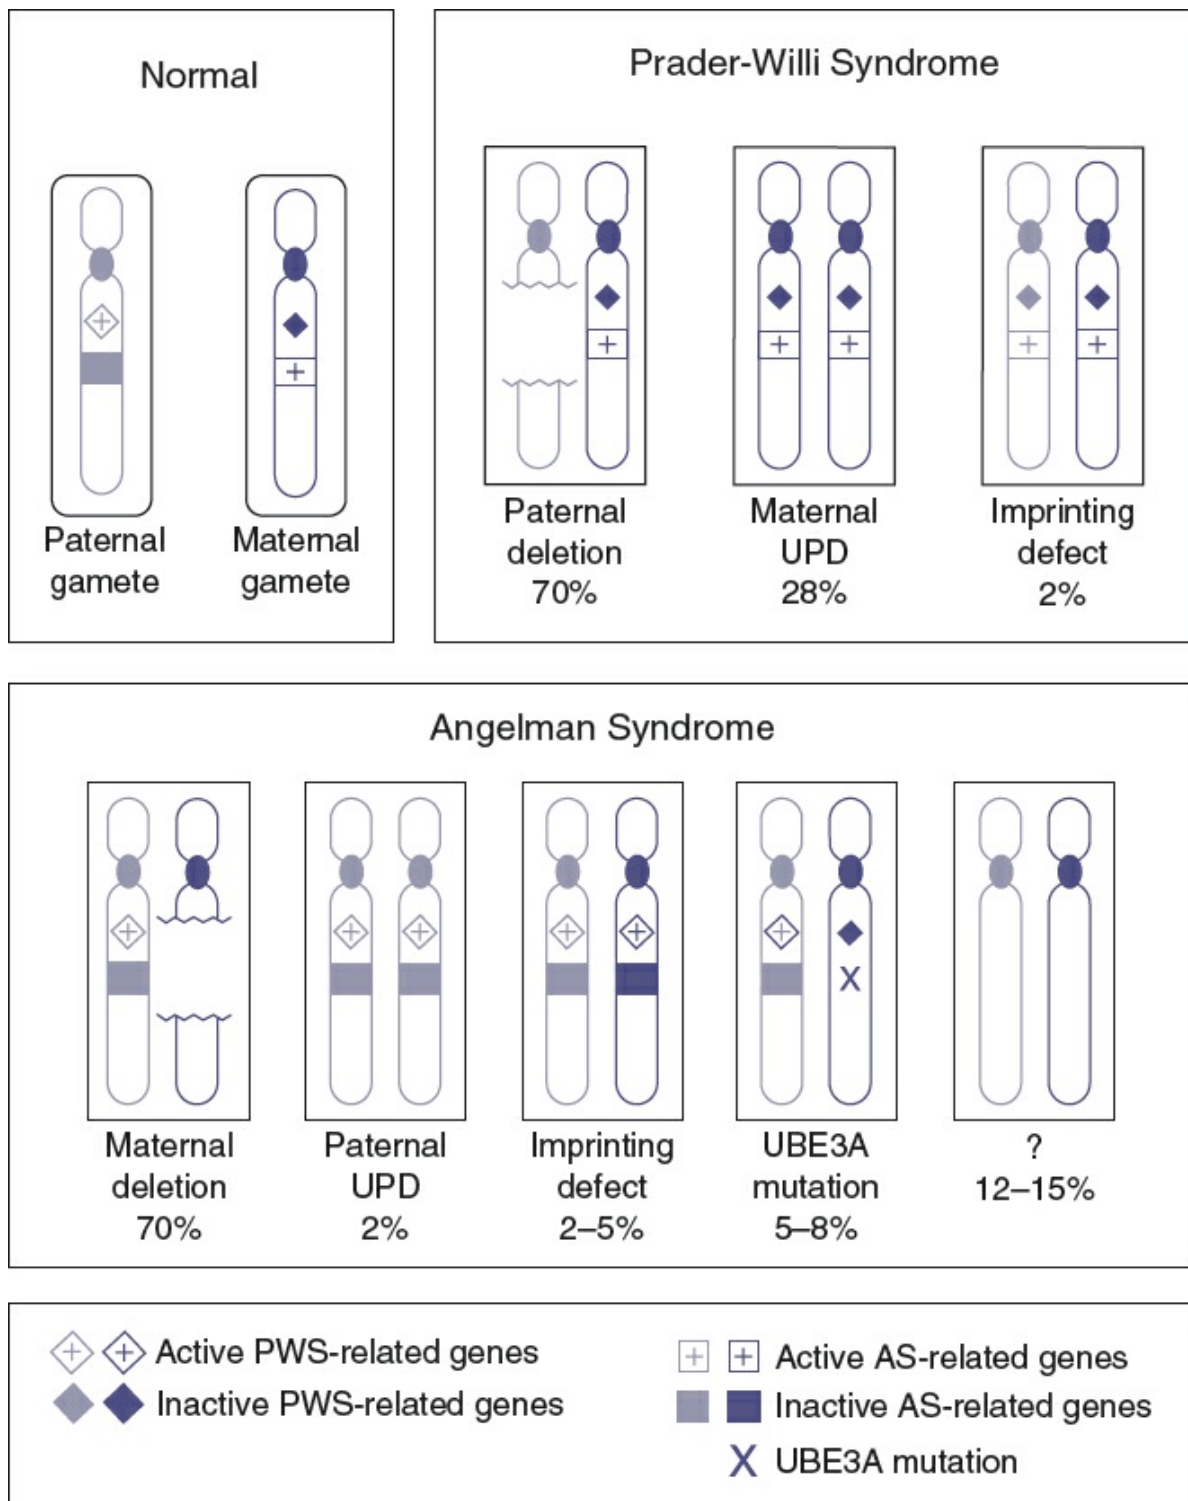
Myotonic dystrophy symptoms	CTG expansion
Cataracts late in life	35–45 repeats
Mildly affected	50–80 repeats
Severely affected	1000–2000 repeats
Fatal congenital disease	>2000 repeats
FIGURE 3.3.3.4. Anticipation. Anticipation refers to the increase in severity for a disorder over several generations. In myotonic dystrophy, for example, the increase in symptoms ranges from cataracts late in life in a great-grandfather, to milder symptoms in a grandfather and more severe muscle disorder in the father, to fatal congenital illness in the proband. A corresponding increase is found in the triplet repeat expansion for cytosine-thymidine-guanine (CTG).


FIGURE 3.3.3.5. Imprinting in Prader–Willi and Angelman syndromes. Imprinting refers to the silencing of certain genes. It is a stable and reversible event that depends on the parental origin of the chromosome on which the gene lies and results in repression of a gene. For some genes, the paternal gene is silenced, whereas for other genes, it is the maternal gene. On chromosome 15, two adjacent regions are imprinted. In the normal situation (shown in the left, top panel), genes in the Prader–Willi syndrome (PWS) region are expressed on the paternal chromosome, whereas genes in the Angelman region are imprinted. The opposite situation exists on the

maternal chromosome: genes in the PWS region are repressed, whereas genes in the Angelman region are expressed. Three mechanisms for developing PWS are shown, whereas four mechanisms have been discovered for Angelman syndrome (AS). The key at the bottom indicates genes, imprinting patterns, and mutations in both disorders. The relative proportion of each type of genetic abnormality in each syndrome is also shown. UPD, uniparental disomy. (Adapted with permission from Everman D, Cassidy S: Genomic imprinting: breaking the rules. *J Am Acad Child Adol Psychiatry* 39:386–389, 1999.)

These two nearby regions on chromosome 15 are differentially imprinted. Normally, genes within the PWS region are expressed on chromosomes that derive from the father. Immediately downstream a second set of genes lie within the Angelman critical region. These paternal-derived genes are imprinted and not expressed. The opposite expression pattern is found on the maternal chromosome. Genes within the PWS region are silenced, whereas genes within the Angelman region are expressed (Figure 3.3.3.5) (119,120). Deletions are responsible for approximately 70% of cases of both PWS and Angelman syndrome. In most cases, specific proximal and distal breakpoints have been identified that flank a portion of the chromosome and cause the approximately 5- to 6-Mb deletion (121,122).

The illnesses may also occur when children receive two copies of chromosome 15 from one of their parents (123). This unusual mechanism is called uniparental disomy (UPD). It occurs after an initial trisomy event in which two chromosomes from one parent are inappropriately passed along with one copy of the chromosome from the other parent, resulting in a total of three (rather than two) chromosomes. One chromosome is lost during gamete formation. If the initial trisomy involves two maternal and one paternal chromosome, then loss of the extra paternal copy results in two maternal chromosomes, or maternal UPD. If the initial trisomy involves two paternal and one maternal chromosome, then loss of the extra maternal copy results in paternal UPD.

Maternal UPD results in PWS (124) and it accounts for approximately 20% to 30% of cases. In this situation, the genes that lie within the PWS region are not expressed on the two maternal chromosomes and no functional proteins are produced. Paternal UPD represents the opposite situation. PWS genes are present on both paternal chromosomes and both sets are expressed. However, the genes that lie within the Angelman region are imprinted on the paternal chromosomes; therefore, even though there are two copies of all the genes, both sets are repressed and no proteins are expressed.

A third mechanism that leads to these disorders involves a region of DNA called the imprinting center. This center controls imprinting by regulating the extent of

methylation and chromatin compaction for hundreds of kilobases of DNA on either side. It appears that one center determines the state of imprinting within both the PWS and Angelman critical regions. Mutations within the imprinting center have been discovered that lead to inappropriate imprinting or a lack of imprinting where it should normally occur. These types of mutations cause PWS or Angelman syndrome in about 2% to 3% of affected individuals (125). Mosaic methylation imprinting defects were recently reported in association with mild developmental impairment. This led to the hypothesis that undiagnosed groups of individuals with mild cognitive impairment could be explained on the basis of a mosaicism in the DNA imprinting center (126).

Finally, a fourth mechanism causes Angelman syndrome in approximately 10% of the cases. This is a mutation within a single gene lying within the Angelman critical region called UBE3A (127–129). The protein encoded by this gene normally regulates the lifespan of other proteins within the cell by regulating their degradation (Figure 3.3.3.6).
FIGURE 3.3.3.6. Angelman syndrome. It is critical to remove unwanted proteins from within cells before they disrupt cellular metabolism. Several steps are involved in this process and lead to the addition of one or more ubiquitin molecules to proteins targeted for degradation. The addition of ubiquitin to the protein serves as a signal to the proteasome, an organelle that breaks down proteins and serves as the cellular equivalent of a garbage disposal for a cell's unwanted proteins. (Adapted with permission from Lombroso PJ: Genetics of childhood disorders: XVI Angelman syndrome. *J Am Acad Child Adol Psychiatry*, 39:931–933, 2000.)

Many proteins must be quickly degraded and removed from the intracellular

environment to ensure proper cell function. These include signaling proteins in which rapid turnover permits repeated signaling. It is also critical to remove certain enzymes that have become damaged before they interfere with normal intracellular signaling pathways. Several copies of a small molecule are added to proteins destined for degradation. This molecule, ubiquitin, acts as a flag to target the protein for degradation. The protein product of *UBE3A* is required in this process (32,42,107,128). It is one of several proteins that act in sequential order to attach ubiquitin molecules to targeted proteins. Intracellular organelles called proteasomes recognize ubiquitinated proteins, bind to them, and activate proteases that degrade the protein into its constitutive amino acids. When this protein is mutated and unable to function properly, an inappropriate accumulation of proteins within CNS neurons disrupts normal function. Thus, elevated peripheral BDNF levels were reported in patients with Angelman syndrome compared to neurotypical controls, which was interpreted as the consequence of deficient *UBE3A* expression (130).

The *UBE3A* gene encodes the E6-associated protein (E6AP), also known as ubiquitin-protein ligase E3A, whose function is to transfer ubiquitin from E2 ubiquitin-conjugating enzyme to its substrate, a process that eventually results in its degradation. This function is mediated by a specific domain termed the HECT domain. The silencing of the paternal allele at this locus is mediated by a nuclear localized, noncoding RNA antisense transcript (*UBE3A-ATS*) (131,132). Recently, it was reported that unsilencing of this allele by means of antisense oligonucleotides targeting the *UBE3A-ATS* transcript partially restored the expression of the UBE3A protein and ameliorated cognitive impairment in mice (133).

Several target proteins that are ubiquitinated by E6AP have been identified, including the tumor suppressor p53, MCM7 (a protein involved in DNA duplication), Arc, MecP2, and TSC2 (134–136). Alterations in a potassium channel were recently reported in the hippocampus of *UBE3A*-deficient mice with impaired synaptic strengthening and LTP (137). Disruption of activity-dependent phosphorylation of ERK1/2 has also been observed in *UBE3A*-deficient mice (138).

More than 150 pathogenic variants in *UBE3A* gene have been observed, mostly involving frameshifts (139). Interestingly, mutations that increase the activity of UBE3A lead to another developmental disorder. Thus, duplication of the region on the maternal chromosome region where *UBE3A* is found (Dup15q syndrome) is associated with developmental delays, autism, speech deficits, and epilepsy (140–142). These results indicate that the activity of UBE3A is tightly regulated within neurons. A recently reported mechanism that regulates UBE3A activity is the phosphorylation of UBE3A (142). A high rate of mutations is concentrated in a particular region within UBE3A containing a threonine residue that is phosphorylated. Phosphorylation at this residue leads to the inactivation of UBE3A within neurons that contributes to the tight regulation of UBE3A activity. Mutations that change the threonine residue result in a UBE3A mutant that is constitutively

active and also leads to developmental delays and autism; in contrast, mutations that decrease UBE3A activity lead to Angelman syndrome.

Several enzymes in addition to UBE3A are required for the enzymatic reactions that result in the addition of ubiquitin molecules to proteins targeted for destruction. Mutations in these genes may lead to similar clinical problems. Such mutations would represent examples of locus heterogeneity in which mutations in distinctly different genes produce similar phenotypes. A number of laboratories are actively investigating this possibility.

On the other hand, no single gene mutation has yet been found in patients with PWS, and it remains unclear whether the absence of a single gene or the deletion of several genes within the critical PWS region is necessary for the disorder. Several genes were mapped to the region affected by the deletion, including the growth suppressor *NECDIN* and the ubiquitin ligase modulators *MAGEL2* and *MKRN3*. Truncating mutations in *MAGEL2* were recently described in four individuals with intellectual disabilities, autism spectrum disorder, and hyperphagia (143). This chromosomal region also contains a bicistronic gene that encodes two different proteins, the small ribonuclear protein SNRPN and a protein identified as SNRPN upstream reading frame (SNURF). The 5' region of this gene has been identified as an imprinting center. The SNRPN/SNURF locus controls the expression of several small nucleolar RNAs (snoRNA), which are located in the chromosome telomeres (144). SnoRNAs are noncoding RNAs whose function has not been fully elucidated, but they may be implicated in the modification (by methylation or splicing) of other small RNAs involved in telomeres maintenance. Two snoRNAs in the PWS region of the chromosome 15 have been identified, *SNORD115* and *SNORD116*, which are present in 29 and 42 tandem repeats respectively. Specific targets of these snoRNAs have not been characterized yet, with the exception of serotonin 2C receptor for *SNORD115*, although a recent study in families carrying specific deletions and translocations allowed investigators to narrow down the PWS phenotype to *SNORD116* gene cluster (145). Additionally, mice carrying mutation at the *SNORD116* locus displayed PWS-like phenotype, including hyperphagia and growth retardation (146,147).

Two final notes should be made regarding Angelman syndrome. Recent work suggests that the maternally imprinted genes are differentially imprinted depending on the brain region where they are expressed (148). In addition, one of the genes within the region deleted in Angelman syndrome encodes a subunit of the GABAa receptor (149). The absence of this gene and a related disturbance in GABA transmission is believed to be responsible for the seizure disorders in individuals with the full deletion syndrome. As expected, individuals with a point mutation within only the UBE3A gene do not have epilepsy.

WILLIAMS SYNDROME

Deletions that span a number of adjacent genes and cause a constellation of symptoms are called contiguous gene syndromes. Williams syndrome is one such disorder, caused by a deletion of 25 genes located on chromosome 7 (7q11.23). This developmental disorder is characterized by distinct facial features, a variable degree of cognitive disability, cardiovascular disease, and a very distinctive cognitive profile characterized by attention problems, an unusual cheerful demeanor, social disinhibition, and nonsocial anxiety (150,151). The cognitive problems consist of visual–spatial deficits. Affected children are unable to integrate the parts of a picture into a whole pattern (152). Interestingly, these children frequently exhibit strengths in other cognitive areas, such as verbal skills. Indeed, some elements of their speech are normal, such as the quality of their vocabulary, auditory memory, and social use of language. Moreover, many patients sing or play musical instruments with considerable talent. The disorder, first described by Williams in 1961 (153), has a rather low prevalence of 1 per 20,000 live births, although other estimates have suggested the prevalence is as high as 1 in 7,500 (154), and remains a topic of considerable interest because of the striking disparity in cognitive strengths and weaknesses (153,155–157). This disparity raises the possibility that the gene(s) responsible for Williams syndrome influence(s) the development of specific cortical regions and related cognitive abilities. This is in contrast to other forms of cognitive disabilities, such as fragile X syndrome, where a more uniform effect occurs across many cognitive skills.

Functional imaging studies have helped clarify some of the underlying neuropathologic mechanisms in Williams syndrome (158). Investigators of one rigorous study of the observed visuospatial difficulties identified a localized region within the dorsal pathway of the visual system around the intraparietal sulcus. Jernigan and Bellugi (159) examined MRIs of IQ- and age-matched subjects with Williams and Down syndromes. The cerebral cortices of both groups showed an overall decrease in volume. Cerebellar size, on the other hand, was normal among the Williams syndrome subjects but significantly hypoplastic among Down syndrome subjects.

Jernigan et al. extended this study by focusing in greater detail on the morphologic abnormalities in the cortices of subjects with Williams syndrome (160). The overall volume of the cerebral cortex was reduced compared to normal subjects, with relative sparing of the frontal areas and limbic structures, as well as a greater degree of hypoplasia in more posterior cortical structures. Different cortical regions are apparently affected to different degrees in Williams syndrome. MRI studies suggested the decrease in size was particularly prominent in the parietal lobule and occipital gray matter, with preserved cerebellar size; white matter decrease was estimated to be approximately 18% (161,162). Gray matter volume reductions were also documented in a cohort of high-functioning individuals with Williams syndrome

in the intraparietal sulcus, the hypothalamus, and the orbitofrontal cortex. Additional morphologic changes occur in the brain of individuals with Williams syndrome, including flattening of the corpus callosum and abnormal protrusion of the cerebellum into the spinal canal (Chiari malformation), as well as increased gyrification in the parietal, temporoparietal, and occipital areas, and length reductions in the central gyrus (163–166).

Additional morphologic data comes from the autopsy of a Williams subject. Galaburda et al. (167) found abnormal organization among the neurons in posterior cortical regions (area 17), an increase in cell packing density throughout the cortex, and abnormal neuronal clustering. This result was recently confirmed by another study from the same group, where altered cell size and density were documented particularly in the primary visual cortex (168), although this single autopsy report requires additional work to clarify the underlying pathologic process.

Together, these findings suggest that abnormal, nonuniform development of the cerebral cortex may be responsible for the nonuniform cognitive findings that characterize these patients. The relatively intact cognitive skills related to affective recognition, face processing, and linguistic skills may be a consequence of the relatively normal development of limbic and frontal cortices and perhaps the relatively normal cerebellar structures. Poor functioning in visuospatial skills may be due, at least in part, to the abnormalities in the posterior cortical structures, such as the parietal and occipital cortices known to be involved in visual processing. It is reasonable to suggest that the gene or genes affected in Williams syndrome may have their greatest impact on the development or normal functioning of more posterior regions of the cerebral cortex.

Nearly all patients with Williams syndrome have a large deletion of a segment of chromosome 7, in the Williams–Beuren syndrome critical region (WBSCR) (169,170). The deletion encompasses a region of approximately 1.55 Mb in 95% of individuals with Williams syndrome. Phenotype severity correlates with the extent of the deletion; individuals with shorter deletions not including the *GTF21* locus at the telomeric breakpoint retain the peculiar cognitive profile, but without intellectual disabilities (171). A number of researchers note that cardiovascular symptoms cosegregate with a gene in the deleted region for elastin, which is a major component of skin, blood vessels, and lung tissues. The haplodeficiency caused by the deletion of elastin is likely to cause the vascular abnormalities and characteristic facies in these patients (169). Elastin, however, is not detectable in fetal or adult nervous tissue and probably does not contribute to the cognitive abnormalities (172).

Tassabehji et al. (173) were the first to report the deletion of a second gene in 20 out of 20 Williams syndrome patients. The sequence of this gene is nearly identical to a previously characterized gene called LIM kinase 1. Because it is expressed in high concentrations in the brain (174,175), mutations in this gene are possible candidates responsible for the cognitive deficits in Williams syndrome (176). LIM kinase is

involved in growth cone motility in cultured neurons (173). In fact, LIM kinase knockout mice show abnormal dendritic organization, disrupted LTP, abnormalities in synaptic morphology, and deficits in learning (177). Intriguing cognitive deficits in these mice include difficulties with "unlearning." For example, once they have learned the position of a hidden platform in the Water Maze test, they are unable to learn the new location for the platform, something that normal mice can do (177).

For a brief period, it was thought that elastin and LIM kinase 1 were the only genes within the deleted region. It is now known that approximately 25 genes are present within the Williams syndrome critical region (Figure 3.3.3.7). In addition to elastin (152,168) and the LIM kinase 1 (170,171), other genes include *syntaxin 1A* (178), *Cyln2* (179), and *Frizzled 9*, a receptor for Wnt signaling (180), the gene encoding the replication factor C subunit (181), and the general transcription factors *GTF2I* and *GTF2IRD1* (182). Several laboratories are currently investigating the function of these genes (183). *Cyln2* is a protein that controls dynamic aspects of the cytoskeleton through the microtubule network; deficit of this protein is thought to be responsible for the decrease size of the corpus callum detected in individuals with Williams syndrome (184). *GFT2I* and *GFT2IRD1* are two related genes in a cluster on chromosome 7. GFTI2RD1 has strong gene repression capabilities, a DNA-binding site and plays a role in chromatin regulation (185,186). Recently, multivariate pattern classification analysis aimed at integrating morphometric brain pattern, genetics, and behavioral correlates in Williams syndrome suggested an association between (i) *GFT2I/GFT2IRD1* and visuospatial motor integration and intraparietal structures, (ii) the DNA region containing the LIM kinase gene associated with social cognition and with orbitofrontal, amygdala, and fusiform anatomy, (iii) while *syntaxin 1* and *Cyln2* was associated with overall white matter organization (187).

FIGURE 3.3.3.7. Williams syndrome. The deletion at 7q11.23 in patients with Williams syndrome contains at least 16 genes. Several of these genes are expressed within the central nervous system. Shown are candidate genes for the neuropsychiatric symptoms observed in subjects with Williams syndrome. When several genes contribute to the expression of a disorder through their deletion, the illness is termed a contiguous gene syndrome.

RETT SYNDROME

Rett syndrome is a disorder within the autism spectrum (188) with a prevalence of 1 in 8,500 (189). Affected children develop normally and reach developmental milestones within the first year of life and parents are unaware of any abnormalities. One of the first clinical symptoms is the loss of purposeful hand movements. Other clinical findings soon emerge, including loss of speech, growth retardation with microcephaly, ataxia, and a severe disruption of normal cognitive functioning. Clinical symptoms stabilize for the next several decades of life after this initial rapid regression (190).

One unusual feature of the disorder is that females are almost exclusively affected. An early explanation for the preponderance of affected females is that the mutated gene is located on the X chromosome. There are many examples of X-linked disorders in which males die in utero because males only have one X chromosome and only a single copy of the gene in question. Females have a second copy of the gene on their other X chromosome, and it appears that transcription of this gene in a subset of cells provides some degree of protection during fetal development and early postnatal life. However, symptoms eventually emerge because haploinsufficiency, a single functional copy of a gene, is unable to confer lasting protection.

The chromosomal location for the gene at Xq28 was facilitated by analysis of affected sisters (191). Candidate genes known to be present in this region were systematically excluded when their nucleotide sequences revealed no mutations compared to the identical sequences from normal individuals. On the other hand, a gene that is mutated in several affected individuals encodes the methyl CpG–binding protein 2 (MeCP2).

How are mutations in this gene related to clinical symptoms? As discussed in the previous chapter, many genes are expressed in certain tissues and not in others. Of the approximately 20,000 protein-coding genes on the human genome, only about one-third are expressed exclusively within the CNS. Some of these genes and their protein products are important for normal development during critical periods of brain development. Others are needed only after birth, whereas others must be expressed at all times because they are involved in normal housekeeping functions

required of the cell. This functional heterogeneity illustrates how carefully gene expression must be regulated for normal development and maintenance of tissues to proceed.

The previous chapter reviewed how transcription factors and other regulatory proteins such as enhancers and repressors bind to promoter regions of genes and either initiate transcription of specific subsets of genes or maintain their stable repression. The proteins involved in these regulatory events bind to specific DNA sequences within the promoter regions that control gene expression. A protein mutated in Rett syndrome plays a critical role in this process.

The accessibility of DNA sequences depends to a large extent on the degree of methylation within the regulatory regions (192). Methylation is a chemical modification to DNA that occurs when methyl groups are added to cytosine nucleotides. It is particularly prevalent in regions of DNA that contain a high content of cytosine and guanine pairs, so-called CpG islands. Although CpG islands are present throughout the genome, they are enriched within the promoter regions of genes. In fact, one approach to identifying transcriptional start sites is to look for CpG islands because they are often found immediately upstream of the transcriptional start site.

It was originally thought that DNA methylation alone was capable of repressing gene expression. RNA polymerase II is the enzyme that transcribes most DNA into RNA. Methylation of CpG islands within promoter regions was initially believed to be sufficient to prevent this enzyme from gaining access to these regions of DNA and initiating transcription; however, what actually occurs is somewhat more complicated.

The protein implicated in Rett syndrome, MeCP2, has two functional domains. One end of the protein recognizes methylated cytosines and binds tightly to them (MBD). The second domain is then activated and functions by recruiting another set of proteins, the histone deacetylase complex, to the immediate vicinity (TRD). Histones are a family of proteins present within the nuclei of all cells. Their role in modifying the secondary structure of DNA has been recognized for some time because they provide a core of protein around which the chromosomal DNA is wrapped (193). The histone deacetylase complex that has been recruited by MeCP2 chemically modifies histones. The result is a compaction of the DNA surrounding the promoter region such that the transcriptional machinery of the nucleus is no longer able to gain efficient access to the gene, effectively silencing it.

The initial report on Rett syndrome identified six distinct mutations among the patients who had a mutation of their MeCP2 gene (194). To date, 487 pathogenic variants have been characterized, particularly in the two functional domains, MBD and TRD (Figure 3.3.3.8) (195). Most mutations are de novo and several types of mutations have been characterized, including silent, missense, nonsense, and frameshift mutations. In most cases, they result in the formation of truncated proteins

that may still retain the capacity to bind to the target DNA, but are not able to recruit corepressor molecules (e.g., Sin3A) and form proper silencing complexes. Recently, it has been proposed that MeCP2 acts as a transcriptional activator as well (196), and plays a role in gene splicing and chromatin remodeling (197,198).

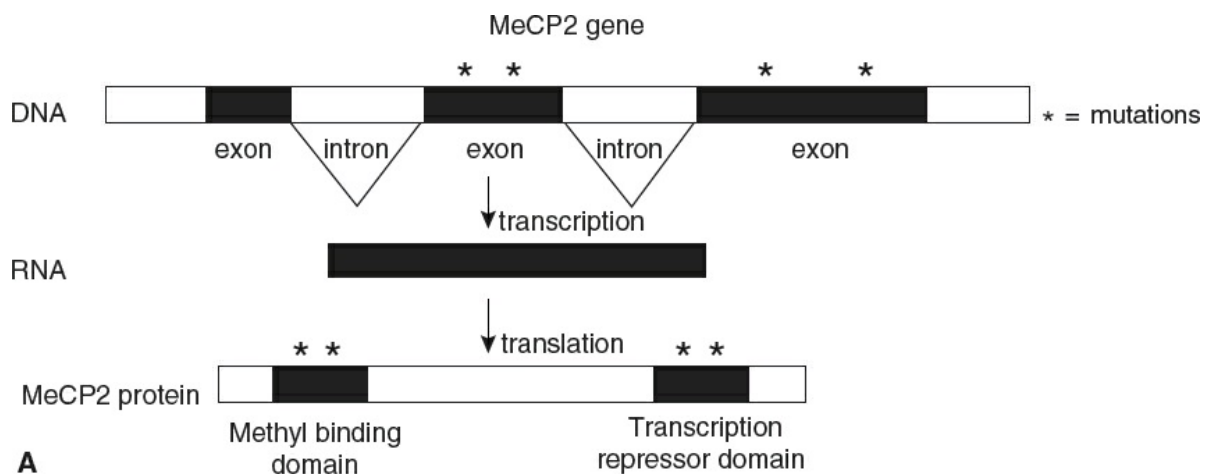
Missense mutations replace critical amino acids within the protein. Mutations of this type are located within the methyl-binding domain and disrupt the ability to recognize and interact with methyl groups. The remaining mutations are found in the second functional region, the domain that recruits the deacetylation complex. Two types of mutations have been found in this second domain. One is the insertion of a single nucleotide that leads to a shift in the downstream codons. A shift such as this results in the translation of a new amino acid sequence downstream of the point of mutation. The second mutation results in a novel stop codon. This type of mutation leads to the production of a truncated protein. Each of the mutations results in an impaired or nonfunctional protein (194).


FIGURE 3.3.3.8. Rett syndrome. **A:** The MeCP2 gene consists of

three exons separated by two introns. The exons are spliced together to produce a mature RNA message that is translated into MeCP2 protein. The gene has been implicated in Rett syndrome after several mutations were found within the coding regions in a number of patients. These are indicated by asterisks (*) in the nucleotide sequence and protein. Mutations to date have been found to change the amino acid sequence within two functional domains of the protein. **B:** MeCP2 protein, through one of its functional domains, binds to methylated cytosine nucleotides present in CpG islands that are enriched within regulatory regions of many genes. After binding to DNA, the second functional domain is activated and recruits a deacetylase complex that chemically modifies nearby histone molecules. The chemical modification of histones leads to a further compacting of the DNA into chromatin. The transcriptional machinery, including DNA polymerase II, no longer has easy access to the underlying DNA and is unable to initiate transcription. (Adapted with permission from Lombroso PJ: Rett syndrome. *J Am Acad Child Adol Psychiatry*, 38:671–674, 2000.)

Only certain regions of the MeCP2 gene were actually sequenced in this initial study: those that contain the open reading frame, or that portion of the gene that encodes the protein. These regions are often analyzed first because they require far fewer nucleotides to be sequenced compared to an analysis of the entire gene with its multiple introns and regulatory regions, and are therefore considerably less expensive to conduct. However, mutations in regulatory regions or in introns can also disrupt gene expression. For example, mutations at a promoter area may interfere with the initiation of transcription, whereas mutations in introns may interfere with the splicing of exons by disrupting a splice site regulatory sequence.

As mentioned earlier, allelic heterogeneity refers to the presence of different mutations within a single gene. In the majority of disease-causing mutations studied so far, the same or a very similar clinical phenotype is seen when different functional domains of a single gene are mutated. This type of allelic heterogeneity was demonstrated in the initial study on Rett syndrome (194). Six distinct mutations were found in different regions of the same gene, yet all the patients had the same disorder. It is likely that additional mutations will be found within regulatory sequences of MeCP2 that result in a similar phenotype. On the other hand, mutations to a single gene occasionally cause very different clinical presentations. For example, several mutations within the receptor for the fibroblast growth factor are responsible for a number of distinctly different skeletal and growth abnormalities (199).

By way of contrast, locus heterogeneity refers to mutations in different genes that

result in a similar clinical presentation among affected individuals. This can happen, for example, when several proteins are involved in a series of related enzymatic reactions. For example, MeCP2 encodes one member of a larger family of proteins. At least two other members have been discovered that also bind to DNA and are involved in the recruitment of the histone deacetylation complex. Each of these proteins is now being examined to determine whether mutations in their genes also cause Rett syndrome. Moreover, as discussed, a number of proteins besides MeCP2 are required to repress target genes. Mutations of any of these other genes may result in a related clinical phenotype. In fact, mutations have now been documented in a second gene that results in a clinical phenotype very similar to Rett syndrome (200,201). Aside from the congenital form, several atypical variants of Rett syndrome have been recently described, including the preserved speech variant and the early-onset seizures variant. With particular regard to the latter, a mutation at the *CDKL5* locus was described. Similarly, a mutation in the repressor gene *FoxG1* was also described in a 7-year-old girl exhibiting intellectual disabilities, facial dysmorphisms, and Rett-like features (202). Autistic and Rett-like features were also recently described in an individual with a de novo heterozygous deletion in chromosome 2, with no abnormalities at the *MeCP2* locus (203).
